CONTENTS

PAPERS

No.		PAGE
1480	**THE FLOOD OF JUNE, 1921, IN THE ARKANSAS RIVER, AT PUEBLO, COLORADO.**	
	By James Munn and J. L. Savage	1
	Discussion:	
	By Arthur O. Ridgway	36
	R. G. Hosea	44
	George G. Anderson	53
	Robert Follansbee and E. E. Jones	61
1481	**RAINFALL AND RUN-OFF STUDIES.**	
	By C. E. Grunsky	66
	Discussion:	
	By Dana M. Wood	106
	C. F. Marvin	111
	Rudolph Hering	111
	Olin H. Landreth	113
	Thaddeus Merriman	114
	R. A. Hill	117
	Kenneth Allen	119
	L. Standish Hall	123
	H. V. Hinckley	130
	Walter E. Jessup	130
	E. W. Clarke	131
	W. W. Horner	132
	C. E. Grunsky	134
1482	**NATIONAL PORT PROBLEMS: A SYMPOSIUM**	137
	NATIONAL PHASES OF PORT PROBLEMS.	
	By Frederick W. Cowie	138
	TERMINALS.	
	By Lansing H. Beach	145
	DEVELOPMENT OF THE SMALLER PORTS.	
	By Frederic H. Fay	157
	RELATION OF WAREHOUSES TO PORT DEVELOPMENT.	
	By M. A. Long	164
	FUNCTION OF PORT TERMINALS AS CLEARING AGENCIES.	
	By J. Rowland Bibbins	168
	LACK OF CO-ORDINATION IN DESIGN OF AMERICAN PORTS.	
	By John Meigs	172
	A BRIEF COMPARISON OF AMERICAN AND FOREIGN SEAPORTS.	
	By W. Watters Pagon	178

No.		PAGE
	SOME OBSERVATIONS ON PORT FINANCES.	
	By Edwin J. Clapp	183
	IMPROVEMENT AND DEVELOPMENT OF PORTS.	
	By Carroll R. Thompson	189
	PORT PROBLEMS IN NEW YORK.	
	By John A. Bensel	192
	RELATIONSHIP OF RAIL AND WATER CARRIERS.	
	By William J. Wilgus	195
	PORT ADMINISTRATION.	
	By B. F. Cresson, Jr	199
	PIER DESIGNS AS DEVELOPED FROM QUAY DESIGNS.	
	By H. McL. Harding	204
	Discussion:	
	By William H. Adams	208
	Arthur M. Shaw	211
	T. F. Keller	215
	Harwood Frost	216
	L. F. Bellinger	218
	John H. McCallum	221
	Frank W. Hodgdon	222
	M. G. Barnes	224
	Nelson P. Lewis	230
	T. Howard Barnes	231
1483	THE CIRCULAR ARCH UNDER NORMAL LOADS.	
	By William Cain	233
	Discussion:	
	By L. J. Mensch	249
	B. F. Jakobsen	254
	Fred A. Noetzli	261
	William Cain	264
1484	THE RELATION BETWEEN DEFLECTIONS AND STRESSES IN ARCH DAMS.	
	By F. A. Noetzli	284
	Discussion:	
	By L. J. Mensch	308
	William Cain	310
	B. F. Jakobsen	320
	Charles P. Dunn	323
	Albert B. Hill	326
	L. Standish Hall	333
	William A. Miller	334
	Chauncy Wernecke	338
	W. H. R. Nimmo	339
	Gardner S. Williams and Albert E. Greene	342
	F. A. Noetzli	345
1485	THE FLOOD OF SEPTEMBER, 1921, AT SAN ANTONIO, TEXAS.	
	By C. Terrell Bartlett	354

Paper No. 1480

THE FLOOD OF JUNE, 1921, IN THE ARKANSAS RIVER, AT PUEBLO, COLORADO*

By James Munn† and J. L. Savage,‡ Members, Am. Soc. C. E.

With Discussion by Messrs. Arthur O. Ridgway, R. G. Hosea, George G. Anderson, Robert Follansbee, and E. E. Jones.

Synopsis

This paper describes the causes and effects of the flood of June, 1921, in the Arkansas River, at Pueblo, Colo., and discusses general plans and estimates for future flood-control works.

A history of former floods is followed by a description of the recent flood, including a discussion of the causes, the resulting property damage, the estimated peak flow and flood volume, the drainage area and rainfall data, and a presentation of alternative plans and estimates for flood-control works.

History of Former Floods

The first flood in the Arkansas Valley known to white settlers occurred in 1864. At that time, Pueblo was little more than a trading post, and the damage was slight. The next flood of unusual volume occurred in 1894. At the time of this flood, Pueblo had little or no river protection, and the Arkansas River meandered through the city, cutting its banks and changing its course. This flood did considerable damage by covering the railroad yards and flooding the city to Third and Fourth Streets. After the flood of 1894, the river channel was straightened and substantial levees were built, leaving the river in the condition obtaining at the time of the flood of June, 1921.

With the exception of a flood in the Purgatoire River, a tributary of the Arkansas, in 1908, which washed out the Fort Bent Canal diversion dam and the Amity Canal diversion dam, there has been little damage to irrigation or

‡ Designing Engr., U. S. Reclamation Service, Denver, Colo.

other works through floods on the Arkansas River or its tributaries in the past twenty years. The minor damages which have occurred from time to time during this period, have been due more to poor construction or insufficient protection than to unusual flood conditions.

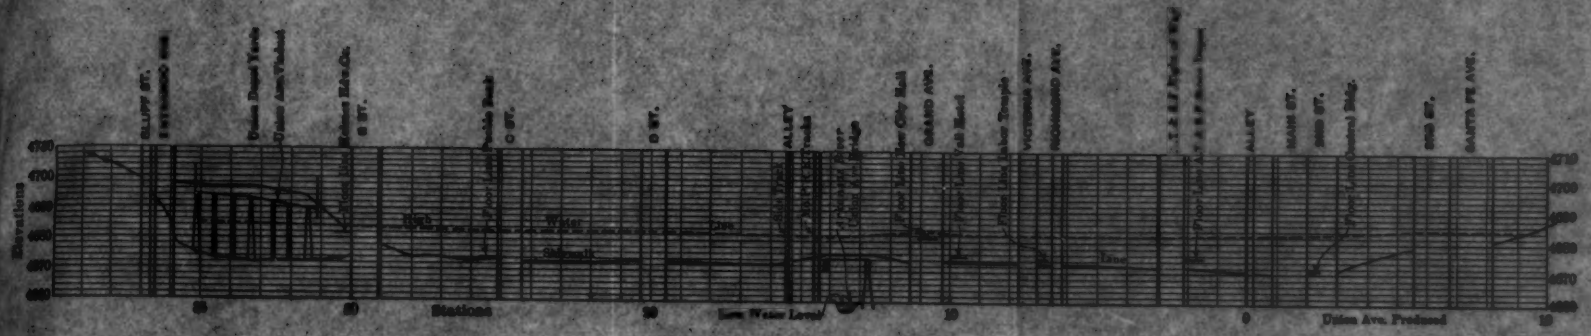
DESCRIPTION OF THE JUNE, 1921, FLOOD

On the afternoon of June 2d, 1921, the Arkansas River at Pueblo was carrying 8 100 sec-ft. At 11.30 P. M., the river began to rise rapidly and, at 2.00 A. M., on June 3d, the discharge was about 28 500 sec-ft. At 8.00 A. M., June 3d, the discharge had dropped to 3 500 sec-ft. and, from noon to 5.00 P. M., it again began to rise rapidly, overtopping the levees and beginning to rise very rapidly, reaching a gauge height of 12.7 ft. and a discharge of 24 000 sec-ft. at 6.40 P. M., where it remained stationary until 7.40 P. M. At 7.40 P. M., it again began to rise rapidly, overtopping the levees and beginning to flood the city at 8.45 P. M., with a gauge height of 18.14 ft.

When the river began to overflow its banks, the discharge was probably about 40 000 sec-ft., but from the time of overflow the quantity of water passing through the city cannot be accurately determined, due to the choking of the channel with débris of all kinds. Subsequent levels showed a maximum gauge height of 24.66 ft., and the peak discharge has been roughly estimated at 100 000 sec-ft. The river after overflowing at 8.45 P. M., on June 3d, continued to rise until about 1.30 A. M., of June 4th, when it began to recede. At 4.30 A. M., it had fallen to a gauge height of about 18 ft., with an estimated discharge of about 50 000 sec-ft.

Sometime during the night of June 3d, a flood came down Fountain Creek, a tributary from the north, which joins the Arkansas River at Pueblo. The peak of this flood has been roughly estimated at 50 000 sec-ft. Although this flood receded quickly, it did considerable damage along its own course and added greatly to the damage in the Arkansas Valley below Pueblo.

On Sunday, June 5th, at about 3.00 P. M., another flood in the Arkansas River swept through Pueblo, adding somewhat to the damage and causing renewed alarm. This flood was caused by the destruction of the Schaeffer Dam on Beaver Creek, which released about 3 100 acre-ft. of reservoir storage. Probably no damage would have resulted from this flood if the levees had not already been breached by the greater flood of June 4th. In this connection, it will be noted that the flood of June 5th, resulting from the destruction of the Schaeffer Reservoir, totaled only 3 100 acre-ft., or about one-thirtieth of the whole flood volume.



The flood in the Arkansas River below its junction with Fountain Creek at Pueblo was augmented to a considerable extent by floods in some of the tributaries entering below Pueblo. The St. Charles River added probably 10 000 sec-ft., and this stream did considerable damage along its own course. At La Junta, Colo., the peak in the Arkansas River was probably between 170 000 and 175 000 sec-ft. Below La Junta, the accretions were negligible, and near Lamar, at the Amity Canal diversion dam, the peak flow was estimated at 170 000 sec-ft.

FIG. 3.—AEROPLANE VIEW OF FLOOD DAMAGE IN RAILROAD YARDS, PUEBLO, COLO.

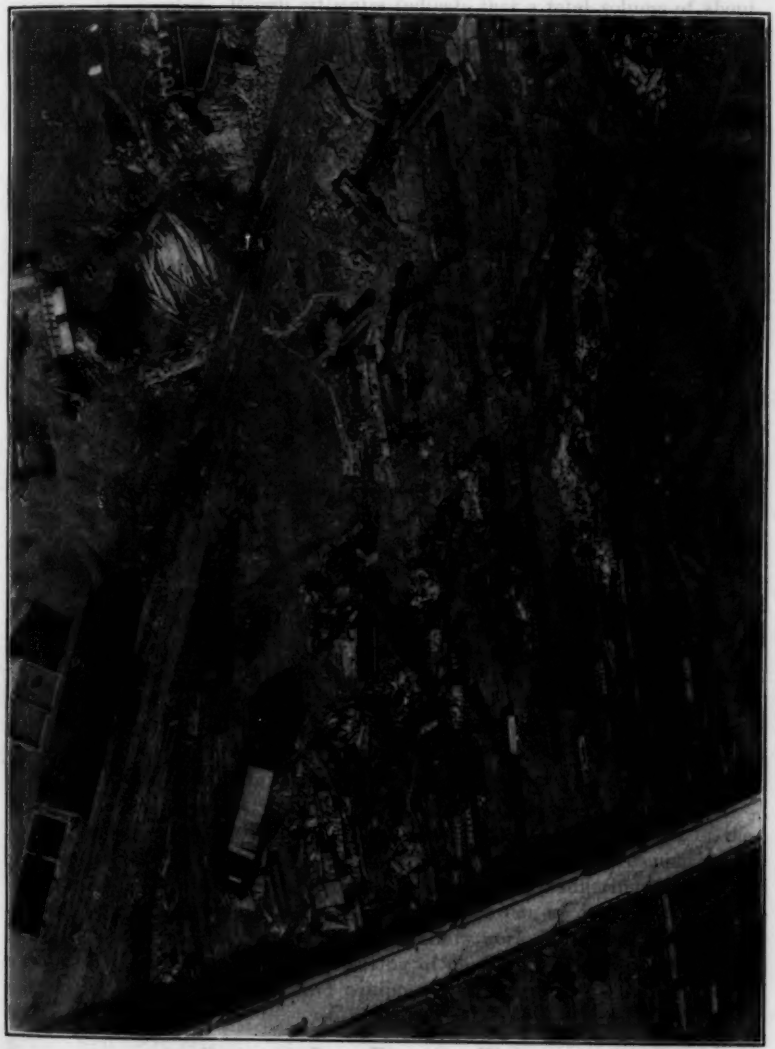

FIG. 3.—AEROPLANE VIEW OF FLOOD DAMAGE IN RAILROAD YARDS, PUEBLO, COLO.

Although the flood peaks, as estimated, were very high, the duration of these high peaks was not long and, consequently, the flood volumes were not as large as might be expected. Rough estimates indicate that a total volume of about 100 000 acre-ft. passed through Pueblo from the Arkansas River and that from about 50 000 to 75 000 acre-ft. was added by the Fountain, St. Charles, and other streams down the valley, during the period of the flood.

FLOOD LOSSES

Preliminary estimates indicate that the property losses will total as follows:

Federal, State, and county	$900 000
Municipal	800 000
Real estate (city and town)	3 420 000
Personal (city and town)	3 575 000
Farm	3 675 000
Irrigation works	1 275 000
Railroads	4 685 000
Public utilities	500 000
Other property not included above	250 000
Total actual damage	$19 080 000

In addition to the damages, as estimated in the foregoing, there are intangible losses which are not covered in the estimates. The loss to railroads, public utilities, manufacturers, merchants, and business concerns generally, from the suspension of business, will aggregate a large sum. Likewise, the depreciation of property values, both within and without the flooded districts, if susceptible of estimate, would add materially to the actual losses.

In connection with the depreciation of property values, it should be noted that the ultimate depreciation will depend to a large extent on the scope of the flood-prevention measures finally adopted. If heroic measures are undertaken, and the City of Pueblo and other interests down the valley are made safe against future floods, the ultimate depreciation of property values will be comparatively little. However, if adequate flood protection is not provided, the depreciation of values will undoubtedly be very great.

The City of Pueblo suffered an actual loss of about $10 000 000 out of the total of $19 080 000. The effect of this loss can be realized by comparing it with the city's assessed valuation of $33 000 000. Besides suffering these staggering losses, the city was left with an expensive clean-up job. Fortunately, the War Department undertook extensive sanitary work, including the cleaning away of mud and débris and the repairing of damage to the city water-works system, furnishing the funds and equipment, in addition to a company of engineers, for such work.

ESTIMATED PEAK FLOW AND VOLUME

Probably the best estimate of the peak flow and the volume of the flood that can be made without extensive field surveys, is contained in a preliminary report to the State Engineer of Colorado, by R. G. Hosea, Deputy State Engineer. This report contains a table which is reproduced herein as Table 1.

TABLE 1.—QUANTITATIVE ESTIMATE OF PUEBLO FLOOD.

Date, 1921.	Time.	Gauge.	Second-feet.	Average second-feet.	Hours.	Acre-feet.
June 2	5.30 P. M.	7.8	7 900

June 3	7.40 P. M.	12.7	24 000			
				34 500	1	2 875
June 3	8.30 P. M.	16.85	45 000			
	(Max. channel could carry)					
June 3	8.45 P. M.	overflow		72 500	5	30 200
June 4	1.30 A. M.	Max.	100 000			
	(Est. from reports)		(Est.)	75 000	3	18 750
June 4	4.30 A. M.	18.0	50 000			
			(Est.)	45 000	4	22 500
Total						96 296

The main part of the flood started at 5.00 P. M. on June 3d, and totaled more than 78 000 acre-ft. in the following 18 hours. At 10.30 A. M., June 4th, the river was still flowing 40 000 sec-ft., as estimated by Mr. Hosea. There is, however, no information on which to base an accurate estimate of the volume added after this time. It is probable that fully 20 000 acre-ft. was added and that the main part of the flood, starting at 5.00 P. M., June 3d, and ending some time during the night of June 4th, totaled about 100 000 acre-ft. Rough estimates indicate that the peak flow in Fountain Creek was about 50 000 sec-ft., and that the flood volume was about 50 000 acre-ft. A hydrograph of the flood in the Arkansas River has been plotted, corresponding with the data given in Table 1, which is shown on Fig. 8.

DRAINAGE AREA AND RAINFALL DATA

The drainage area which contributed to the flood in the Arkansas River through Pueblo, embraces 1 740 sq. miles, between Canon City and Pueblo. The drainage area tributary to Fountain Creek, which creek joins the Arkansas River at Pueblo, includes 930 sq. miles. These drainage areas consist largely of barren land ranging in elevation from 4 600 to 9 000 ft. above sea level. The areas at different elevations are given in Table 2.

The drainage area on the Arkansas River above Canon City, embracing 3 060 sq. miles, contributed very little to the flood, and, in estimating the run-off, this area can be eliminated from consideration. Although the rainfall was quite general over the tributary area of 1 740 sq. miles, the excessive rainfall was confined to a comparatively small part of this area. The total volume of water which passed Pueblo has been estimated at 100 000 acre-ft. and

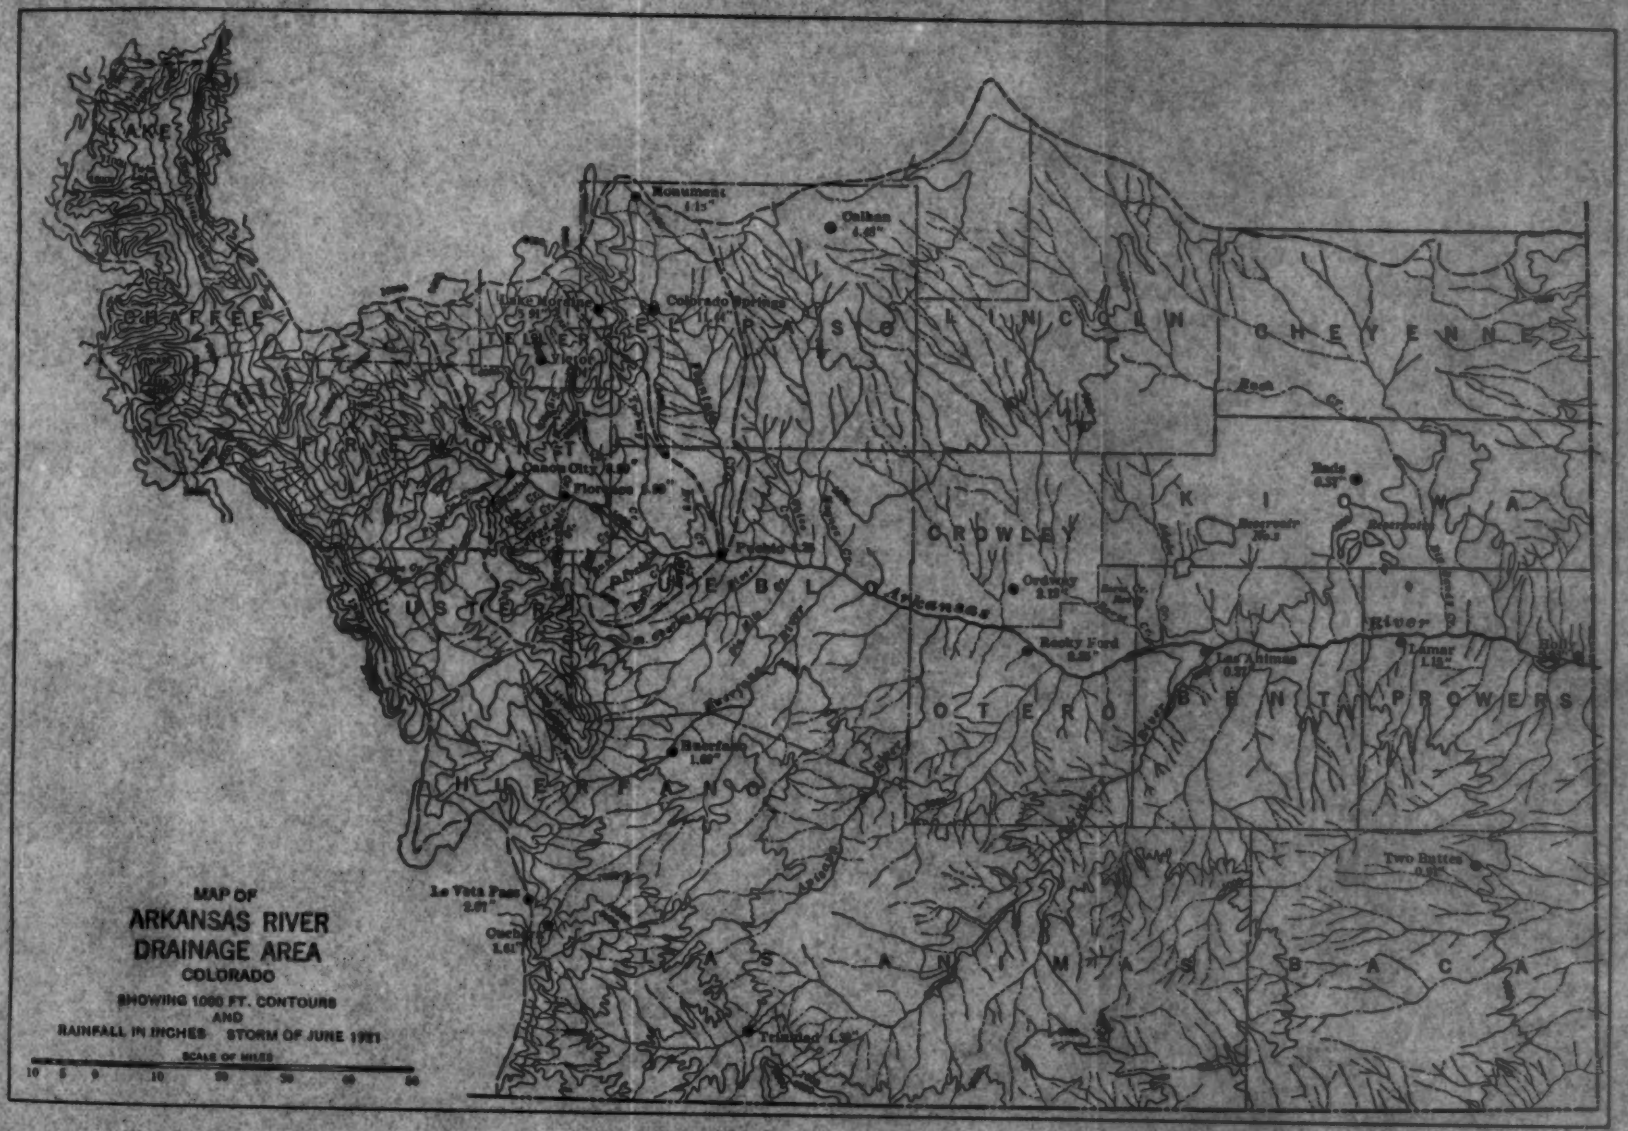
Total	1 740	Total	930



probably one-half this volume came from less than 300 sq. miles of drainage area between Hardscrabble Creek and Pueblo. In this respect, the storm which caused the flood was far from a maximum, and it is probable that a rainfall of an intensity equal to that which fell between Hardscrabble Creek and Pueblo might easily extend over an area of 1 000 sq. miles, resulting in a run-off of more than three times that of the recent flood. The drainage areas are shown in tabular form in Table 3 and in map form on Plate III and Fig. 9.

TABLE 3.—Drainage Area of Tributaries of Arkansas River, Between Canon City and Pueblo, and of Fountain Creek.

Arkansas River, from north:

Fountain Creek		930 sq. miles

In studying the rainfall records of the recent storm, and of other storms in the Arkansas Valley, it is noted that in the two largest storms, namely, those of May, 1894, and June, 1921, the average rainfall increases quite uniformly with the elevation of the drainage area. This relation between rainfall and elevation of drainage area is shown in Table 6, from which the average rainfalls given in Table 7, are taken for the storms of May, 1894, and June, 1921.

Curves showing the average rainfall in 72 hours at different elevations of the Arkansas River drainage area will be found on Fig. 10 for the storms of May, 1894, and June, 1921. Fig. 10 also shows a curve of assumed maximum rainfall in 72 hours, based on 140% of the greatest recorded rainfall in the storms of May, 1894, and June, 1921. It also shows a curve of assumed maximum run-off based on the following assumed percentages of run-off for the different elevations of the drainage area:

Elevation.	Percentage of Run-Off.

Note.—The probable maximum rainfall is estimated to be 40% in excess of the greatest recorded rainfall during the storms of May, 1894, and June, 1921.

* Equivalent to 3½-in. run-off from 1 740 sq. miles.

Using the same storm area that contributed to the recent flood in the Arkansas River, namely, 1 740 sq. miles between Canon City and Pueblo, and applying the assumed maximum run-off rates, as shown on Fig. 10, to respective areas for different elevations of the storm area, a value of 322 000 acre-ft. has been obtained for the probable maximum run-off through Pueblo. The calculation of this quantity is shown in detail in Table 8. A run-off of 322 000 acre-ft. from 1 740 sq. miles is equivalent to an average run-off of 3½ in. Based on this total run-off, a hydrograph (Fig. 11) has been constructed of a shape similar to the hydrograph of the flood of June, 1921, which indicates a probable peak flow of about 168 000 sec-ft. in the Arkansas River through Pueblo. A similar study of the drainage area of Fountain Creek (Table 9) results in a probable maximum run-off of 164 000 acre-ft. and a probable peak flow of 110 000 sec-ft., as indicated on Fig. 12.

RECONSTRUCTION AND FLOOD CONTROL

There is a dearth of accurate topography and other essential data on which to base even the most preliminary studies of flood-control works, and a careful investigation of alternative plans will involve considerable detail survey work before accurate designs and estimates can be prepared.

Based on the fragmentary data available, it appears that careful consideration should be given to three alternative plans for controlling or limiting the damage from future floods on the Arkansas River, as follows:

Plan A.—Flood-detention storage in sufficient capacity to limit the flow through Pueblo to the present channel capacity of about 25 000 sec-ft.;

Plan B.—Channel enlargement through Pueblo of sufficient capacity to pass the maximum peak flow;

Plan C.—A combination of flood-detention storage and channel enlargement.

Preliminary studies suggest the careful consideration of four alternative plans for limiting the damage from future floods in Fountain Creek, as follows:

Plan D.—Flood-detention storage;
Plan E.—Bank protection along both banks of the flood-plain;
Plan F.—Channel enlargement;
Plan G.—A combination of flood-detention storage with either bank protection or channel enlargement.

Flood Control on Arkansas River

Plan A.—A solution of the problem by flood-detention storage alone would involve the construction of one or more detention reservoirs of sufficient capacity to retard all waters in excess of the present channel capacity through Pueblo, estimated at 25 000 sec-ft. Based on the assumed maximum flood in the Arkansas River, represented in the hydrograph shown on Fig. 11, detention storage of 210 000 acre-ft. would be required to control the flow through Pueblo to 25 000 sec-ft.

The Rock Canyon Reservoir site, on the Arkansas River, about 8 miles west of Pueblo, is believed to be the best site on the river for a detention reservoir. This site is in a gorge in hard sandstone, which formation is known to be of great depth. The floor of the reservoir is privately owned and is partly under cultivation and partly in pasture. The tracks of the Denver and Rio Grande and Santa Fé Railroads, also the upper end of the Bessemer Canal, are in the reservoir site.

Utilization of this site would involve the reconstruction of these railroads for a distance of probably 8 to 10 miles and also some changes in the Bessemer Canal, unless it was considered safe to leave them in the reservoir area. In this connection, it is probable that a flood-detention storage reservoir with large permanent outlets could be utilized for the partial control of unusual floods without increasing the damage from such floods to the railroads or the Bessemer Canal in their present locations. In other words, the railroads and the Bessemer Canal are located so that they are subject to damage from great floods, the damage being principally due to high velocities in the river. With a flood-detention reservoir of large outlet capacity, all ordinary floods would pass the dam without storing water, and only the most unusual floods would submerge the railroads and the Bessemer Canal by storing water in the reservoir. The effect of submergence in comparatively quiet water might cause less damage than the high velocities, under present conditions.

It has been stated previously that a detention storage capacity of about 210 000 acre-ft. would be required to control the assumed maximum flood in the Arkansas River to a flow of 25 000 sec-ft. through Pueblo. Unfortunately, the available data indicate that the Rock Canyon Reservoir site cannot be economically developed to this capacity, and there are probably no other sites of suitable location and sufficient capacity to control the floods. It is concluded, therefore, that Plan *A* may not prove to be feasible, although it should be carefully considered when full data become available.

Fig. 13 shows a capacity curve and Fig. 14 a cost curve for the Rock Canyon Reservoir site from which the costs given in Table 10 are taken. Similarly, Figs. 15 and 16 show a capacity curve and a cost curve, respectively, for the Steel Hollow Reservoir site.

TABLE 10.—COSTS OF STORAGE IN ROCK CANYON RESERVOIR.

Height of dam, in feet.	Reservoir capacity, in acre-feet.	Estimated cost.
75	32 000	$2 000 000
100	61 000	4 000 000
125	100 000	6 500 000

It will be noted that storage in the Rock Canyon Reservoir site is estimated to cost about $65 per acre-ft. Storage on the tributaries, if available at all, would probably cost over 50% more than storage in the Rock Canyon Reservoir, or, say, $100 per acre-ft. On this basis, it might be estimated that 210 000 acre-ft. of flood-detention storage, if available, would cost approximately, as follows:

100 000 acre-ft., at $65	$6 500 000
110 000 acre-ft., at $100 (say)	11 000 000
Total	$17 500 000

Plan B.—A solution of the flood problem on the Arkansas River, based on channel enlargement through Pueblo alone (with no flood-detention storage), would involve the widening and deepening of the present river channel or the construction of other channels, in addition to extensive levee work. In the section of the paper dealing with the drainage area and rainfall data (page 10), it was shown that the peak flow resulting from the maximum assumed storm would be 168 000 sec-ft. This represents the required channel capacity through Pueblo under Plan *B*.

Preliminary studies based on incomplete data indicate that a concrete-lined channel (lined on both sides and the bottom), following in general the alignment of the present river channel, is likely to prove the most economical method of passing the peak flow through Pueblo. Such a channel with a capacity of 168 000 sec-ft., extending from above the Fourth Street Bridge to a point below the Missouri Pacific Bridge, together with the necessary levee construction, is estimated to cost $5 500 000, including excavation, concrete, new bridges, raising of railroad grades, and right of way, as the main items of cost.

Studies have been made on a smaller concrete-lined channel supplemented with grass channels, in the nature of sunken gardens, one on each side of the concrete channel. The additional cost for bridges and for right of way under this arrangement would probably bring the cost to about $7 000 000.

Under Plan *B*, the grade of all bridges should be raised to provide a minimum clearance of 10 ft. between the high-water surface and the lowest

point on the bridge. This provision would probably necessitate raising the railroad grades generally throughout the city, as well as some of the street grades.

It should be noted that the enlargement of the channel through Pueblo, in order to carry the peak flow of the river, would not benefit property interests in the valley below; in fact, it might have the effect of slightly increasing the flood peaks in the lower river.

Plan C.—Another alternative plan for solving the flood problem on the Arkansas River is a combination of flood-detention storage and channel enlargement through Pueblo. Three combinations have been studied, resulting in the estimated costs given in Table 11.

TABLE 11.

Combination number.	Storage.		Channel Enlargement.		Total cost.
	Capacity, in acre-feet.	Cost.	Capacity, in second-feet.	Cost.	
1	32 000	$2 000 000	125 000	$4 500 000	$6 500 000
2	61 000	4 000 000	100 000	4 000 000	8 000 000
3	100 000	6 500 000	67 000	3 000 000	9 500 000

Other combinations can be readily selected from Fig. 19. It is believed that some combination like No. 1, with a comparatively small detention-storage reservoir and a large channel capacity, will prove to be the most economical.

Under Plan *C* the grade of all bridges should be raised in proportion to the channel capacity provided, and it is believed that a clearance of not less than 7½ ft. should be supplied between the high-water surface and the lowest point on the bridge, for channel capacities in excess of 50 000 sec-ft. This provision would necessitate raising the railroad grades, and some of the street grades, as in the case of Plan *B*.

It will be noted that the peak flow in the Arkansas River is quite materially reduced, even with the smallest detention reservoir considered (Combination No. 1), and that it is very considerably reduced with the larger reservoirs. Under Plan *C*, property interests in the valley below Pueblo would benefit in proportion to the detention storage provided.

Summary.—The resulting detention-storage channel capacities and estimated costs for flood control on the Arkansas River at Pueblo under Plans *A*, *B*, and *C* are summarized in Table 12.

FIG. 20.

Although Plan *B* appears to result in the lowest cost, it is believed that some combination of flood-detention storage and channel enlargement under Plan *C* may prove to be the wisest choice. This conclusion is based on the fact that property interests down the valley below Pueblo would benefit by the reduced peak flow under Plan *C*, and also on the belief that this plan may prove to be the most economical when final designs and estimates are prepared, particularly if a plan can be effected by which the railroad tracks would be left in their present location in the Rock Canyon Reservoir area.

Flood Control on Fountain Creek

In its present condition, Fountain Creek is a very serious menace to the City of Pueblo, due to the possibility that another flood might force the stream through the business part of the city, south of Mineral Palace Park. Four alternative plans for flood control on Fountain Creek have been considered and are discussed, as follows:

Plan D.—Under this plan it is proposed to control the floods by detention storage alone. Practically no data are available on which to base studies of possible flood-detention storage on Fountain Creek. However, a rough approximation has been made of a possible site 10 miles above Pueblo (the Steel Hollow Reservoir site) where the topographical sheet of the U. S. Geological Survey (scale, $\frac{1}{2}$ in. = 1 mile; contour interval, 50 ft.) shows a basin of small capacity.

In the section of the paper dealing with drainage area and rainfall data (page 10), it has been estimated that a total volume of 164 000 acre-ft. and a peak flow of 110 000 sec-ft. would result from the maximum assumed storm on the Fountain Creek drainage area. The safe limit of flow in Fountain Creek under present conditions is estimated to be 25 000 sec-ft. From Fig. 20, it will be noted that the maximum assumed storm would be controlled by a detention storage reservoir with a capacity of 73 000 acre-ft., having an outlet capacity of 25 000 sec-ft., corresponding to the safe limit of flow in the present channel. The estimated cost of this amount of storage in the Steel Hollow Reservoir site is $3 000 000. Plan *D* would benefit property interests down the Arkansas Valley below Pueblo by reducing the peak flow in Fountain Creek to 25 000 sec-ft.

Plan E.—A solution of the flood problem on Fountain Creek by bank protection alone has been considered, and this plan appears to have considerable merit. The protective work would probably extend from a point north of the city limits to the junction with the Arkansas River, and would include protection to both banks of the flood-plain. In addition to bank protection, it is believed to be essential that all the bridge grades over Fountain Creek should be substantially raised. This would also necessitate raising the railroad grades in some instances. Preliminary studies indicate that the most effective and economical protection may result from a slope paving of hot, dumped slag, protected at the toe of the slope by interlocking steel sheet-piling. It is believed that Fountain Creek could be made entirely safe by bank protection

of this kind. Plan *E*, of course, would not benefit property interests in the Arkansas Valley below Pueblo, inasmuch as it would have no effect in reducing the flood peaks from Fountain Creek.

Plan F.—Consideration has been given to the possibility of controlling the floods of Fountain Creek by confining the stream in a concrete-lined channel for a reach of about three miles above its junction with the Arkansas River. Plan *F* would also involve raising bridge and railroad grades, as in the case of Plan *E*. Rough estimates show that this plan would cost approximately $2 500 000 for a channel of sufficient capacity to carry the estimated peak flow of 110 000 sec-ft. This plan, it is believed, will warrant careful consideration. It should be noted that Plan *F* would not benefit property interests in the Arkansas Valley below Pueblo.

Plan G.—Another alternative plan for flood control on Fountain Creek is embraced in a combination of flood storage and either bank protection or channel enlargement. Two combinations of detention storage and channel enlargement have been considered, resulting in the costs given in Table 13.

TABLE 13.

Combination number.	Storage.		Channel Enlargement.		Total cost.
	Capacity, in acre-feet.	Cost.	Capacity, in second-feet.	Cost.	
1	25 000	$1 500 000	68 000	$2 000 000	$3 500 000
2	50 000	2 000 000	38 000	1 500 000	3 500 000

Under Plan *G*, the bridge and railroad grades would be raised in proportion to the channel capacity provided. It will be noted that the peak flow in Fountain Creek is quite materially reduced, even with a small detention reservoir. A comparison of the costs under this plan with the cost under Plan *E* or Plan *F* suggests the probability that bank protection alone or channel enlargement alone will prove to be more economical than any combination with detention storage. Property interests in the Arkansas Valley below Pueblo would be benefited in proportion to the reduction of the peak flow in Fountain Creek under Plan *G*.

Summary.—The resulting detention-storage channel capacities and estimated costs for flood control on Fountain Creek under Plans *D*, *E*, *F*, and *G*, are summarized in Table 14.

TABLE 14.

Plan.	Detention storage, in acre-feet.	Channel capacity, in second-feet.	Estimated cost.
D	73 000	25 000	$3 000 000
E	None	110 000	2 500 000
F	None	110 000	2 500 000
G (Comb. No. 1)	25 000	68 000	3 500 000
G (Comb. No. 2)	50 000	38 000	3 500 000

Either Plan *D* or Plan *G* would provide considerable protection against flood damage to property interests down the Arkansas River below Pueblo, and the additional cost for this protection might be warranted. However, the estimated costs of these alternative plans are so close and the data on which they are based are so meager that definite conclusions are impossible as to the most attractive plan.

Irrigation Storage and Power Development

Preliminary consideration has been given to the possibility of utilizing a part of the storage capacity in the Rock Canyon Reservoir site or of providing other storage reservoirs for irrigation use. Some consideration has also been given to the possibility of developing a limited amount of power at the Rock Canyon Reservoir site for municipal purposes and utilizing some of the storage capacity in this reservoir for the domestic water supply of Pueblo.

The total acreage under irrigation in the Arkansas Valley in Colorado is about 450 000 acres. Complete records for sixteen years indicate that the average total run-off of the Arkansas River at Pueblo is 533 000 acre-ft. Rainfall records indicate an average rainfall of 0.86 ft. during the irrigation season from March to November, amounting to 388 000 acre-ft. over the irrigated area of 450 000 acres. The total average rainfall plus run-off at Pueblo is, therefore, 921 000 acre-ft., or only slightly more than 2 acre-ft. per acre, not allowing anything for canal losses by seepage and evaporation, which losses are known to be large. When it is considered that these figures are averages and that there are a great many years when the run-off is materially less, it is evident that the supply for additional irrigation development is very limited. If, however, ample storage capacity was available on the river above Pueblo at reasonable cost, it might prove feasible to develop hold-over storage in sufficient quantity to be of some value in augmenting the supply to present canals or in furnishing a supply to new acreage. This possibility should be given further study when full information is available, notwithstanding the fact that the data at hand indicate no feasible project.

It would not be possible, of course, to utilize any of the flood-detention storage capacity for irrigation storage, and any capacity reserved for irrigation use would have to be additional to the required detention storage. Any capacity developed for irrigation storage in conjunction with a detention reservoir would be at the bottom of the reservoir, and the permanent outlets for detention storage would be placed at the top of the irrigation storage. Irrigation storage located below the permanent outlets would be subject to comparatively rapid silting up and, in this connection, it is believed that the yearly loss by silting might amount to as much as 0.25% of the total average run-off, or about $0.25 \times 533\,000 = 1\,330$ acre-ft. per year. This loss by silting should be given consideration, particularly in the case of a small development for irrigation storage.

The possibility of utilizing a small amount of storage capacity in the Rock Canyon Reservoir site as a domestic supply for the City of Pueblo has been considered, but this plan does not appear to be feasible, due to the fact

that any small reservoir on the main channel of a silt-laden stream would soon be filled with silt. It is believed that the settling reservoir would have to be located off the main stream and fed by a canal similar to the plan now followed. Such an arrangement does not appear to be feasible in connection with the Rock Canyon Reservoir.

The possibility of developing power at the Rock Canyon Reservoir site would depend on whether or not irrigation storage was developed. If no irrigation storage was developed, and the permanent outlets of the detention reservoir were placed at the lowest point in the reservoir, as would be the case, there would be no head for power development. If irrigation storage was developed in any considerable quantity, there might be a possibility of developing a limited amount of power. However, it is believed that very little, if any, firm power would result from such an installation, due to the fact that the development of any considerable irrigation storage would involve holding the water over, possibly for several years at a time.

DISCUSSION

ARTHUR O. RIDGWAY,* M. AM. SOC. C. E. (by letter).—For the sake of clarity in discussing this admirable paper, any comment should conform in sequence to the different sections outlined therein.

History of Former Floods.—A thorough study of all available sources of information indicates that no flood of the magnitude of the 1921 deluge had occurred at the site of Pueblo for at least 100 years previously. Indians and early settlers left stories of a great flood in 1844, but, on investigation, this flood was found to be undoubtedly the result of a tremendous snow which fell in the valley in the early spring and did not entirely disappear for several weeks afterward. The evidence collected shows that although probably of greater volume, because of vastly longer duration, it could not have exceeded in height the flood of 1864. Evidence is also at hand to the effect that, for many years prior to 1844, no such flood as that of June, 1921, could have occurred. That the flood of 1894 substantially exceeded the one which occurred in 1864 has been definitely determined, and that the recent flood of June, 1921, was far greater than the 1894 deluge is not open to question.

In connection with these several floods, the evolution of the channel of the Arkansas River through the site of Pueblo is most interesting and effects a valuable contribution to the information necessary in planning preventative or protective measures. The authors state that at the time of the flood of 1894, "Pueblo had little or no river protection, and the Arkansas River meandered through the city, cutting its banks and changing its course." This is not strictly correct.

Definite data are at hand, which show the various channels of the Arkansas from 1872 to the present time. It is more than probable that the position of the channel in 1872 reflects conditions extant during the flood of 1864. This channel had a greater width than any subsequent channels through the main part of the town, and notwithstanding the fact that the course was very sinuous, its carrying capacity was no doubt quite comparable with that of later channels.

Some time between 1872 and 1881, whether by encroachment of the growing city on the older channel, or by actual channel improvement work, as to which need not now be determined, the channel through the town underwent a decided straightening and narrowing. Its position in the lower part of the city was entirely changed, eliminating a serious detour which existed in the older channel. Between 1881 and 1889, the straightening continued to some extent. The floods of 1889 gave an impetus to channel improvement work, and, by 1894, the channel was practically confined through the built-up part of the city. At the time of the flood of 1894, additional levee work was in progress, especially in the vicinity of the West Fourth Street Viaduct. Subsequently, the levees were completed through the city, the bridges were raised, and the channel otherwise was improved to carry a flood equal in magnitude to that which occurred in that year, the volume of which was determined at the time to be about 40 000 sec-ft. The programme of these improvements was not

* Asst. Chf. Engr., Denver and Rio Grande Railroad, Denver, Colo.

entirely completed until about 1898, since which time little or no additional protective work has been effected. Since the completion of the channel improvements, floods of considerable magnitude have occurred at times, but on no occasion has there been any serious damage and apparently no serious menace. The flood of June, 1921, so far exceeding any of which there is a recorded history, was totally unexpected and no doubt will be included in the list of great American disasters.

Description of June, 1921, Flood.—The Arkansas River at Pueblo quickly receded from flood crest on the night of June 2d, 1921, to nearly normal stage by 8.00 A. M., June 3d, without leaving any ill effects on the channel, and remained at that stage until 5.00 P. M., of June 3d; therefore, only the events which transpired subsequent to that time are involved.

The Deputy State Engineer has fixed the time of overflowing of the channel at the Main Street Bridge, where the river gauge is located, at 8.45 P. M., June 3d, and has computed the discharge of the stream at that time to have been 45 000 sec-ft., with a gauge height of 18.14 ft. The floor of the Union Depot has an elevation equivalent to a gauge reading of 17.61 ft., or 0.53 ft. lower than the coping of the channel walls at the Main Street Bridge. Throughout the night of June 3d, a log was kept in the Union Depot of the various stages of the water, both during its rise and recession. This log, perhaps the only one in existence compiled from actual measurements co-ordinated with accurate and frequent time intervals, shows the stages and duration of the overflow peak, as given in Table 15.

TABLE 15.—FLOOD STAGES AT UNION DEPOT, PUEBLO, COLO., JUNE 3D AND 4TH, 1921.

Time of rise (read up), June 3d.	Gauge height extended, in feet.*	Time of fall (read down), June 4th.
11.55 P. M.	27.36	12.01 A. M.
11.54 P. M.	27.00	12.08 A. M.
11.46 P. M.	26.00	1.03 A. M.
11.41 P. M.	25.00	1.22 A. M.
11.36 P. M.	24.00	1.37 A. M.
11.31 P. M.	23.00	2.02 A. M.
11.10 P. M.	22.00	2.28 A. M.
10.43 P. M.	21.00	3.01 A. M.
10.12 P. M.	20.00	3.47 A. M.
9.43 P. M.	19.00	5.02 A. M.
9.05 P. M.	18.00	7.15 A. M.

* Floor of Union Depot = gauge height of 17.61 ft.

The figures in Table 15 clearly indicate the remarkably short duration of the overflow and the very rapid rise of the river, especially between the hours of 11.31 and 11.46 P. M., when the rate was 1 ft. for each 5-min. period. The subsidence, although phenomenally rapid, was slightly slower. The peak occurred at 11.55 P. M., and not at 1.00 or 1.30 A. M., as heretofore assumed. At no time during the period of either rise or fall does the stage appear to have remained stationary; even the highest stage was only momentary. In view of the position of the Union Depot with respect to the river channel, and considering all the other relevant circumstances, there seems to be no

sound reason for not considering the rise as actually representing conditions on the Main Street gauge. The subsidence at the Union Depot, although in all probability lagging slightly, should be regarded as exactly parallel with that of the channel. The crest at the Union Depot reached a gauge of 27.36 ft., as compared with the reported peak gauge of 24.66 ft., taken from a high-water mark near the Main Street Bridge. Reference of the Union Depot readings, observed in comparatively quiescent water during the progress of the overflow, to the gauge datum has been confirmed by spirit leveling, and there seems to be no question as to their accuracy.

There is little doubt but that the river had fallen to the channel overflow point by about daylight. This is confirmed in a general way by the log at the Union Depot, for with the more than 1 ft. of mud deposited on the depot floor, the observer could scarcely determine just when the water left the structure. In determining the volume of the flood, the important fact for consideration is that notwithstanding the river had fallen to the overflow point at the Main Street Bridge, substantial volumes were flowing, with no insignificant velocities, through other parts of the city from the broken levees near the West Fourth Street Viaduct.

The flood in the Fountain River can now be said with a considerable degree of certainty to have joined the Arkansas River on the eastern outskirts of Pueblo at about 3.00 A. M., on June 4th. This was 3 hours after the peak was reached by the Arkansas, or when that stream had fallen to a stage within 3 ft. of the overflow height. The discharge of the main stream, therefore, could not have been more than 60 or 70% of the peak flow, whatever that was, when it was joined by the Fountain River which from an accurate flood section is now estimated to have carried a maximum of about 40 000 or 45 000 sec-ft.

In a supplemental report, R. G. Hosea, Deputy State Engineer, gives some results of his field investigation of the tributaries of the Arkansas River east of Pueblo, together with a computed rate of discharge of the main stream near La Junta, Colo., 65 miles east of Pueblo. These results are as follows:

St. Charles	50 000 sec-ft.
Chico	20 000 " "
Huerfano	5 000 " "
Arkansas at La Junta	180 000 to 200 000 " "

As flood crests in the tributaries were not synchronous with the main stream, nor with each other, it is more than probable that the maximum discharge of the river at La Junta did not exceed 200 000 sec-ft.

At 9.30 A. M., on June 5th, the Schaeffer Dam, an earthen structure, 90 ft. high, on Beaver Creek and about 11 miles from its junction with the Arkansas, failed with a crash. The impounding reservoir, estimated to contain about 4 000 acre-ft. at the time of failure, was emptied in 30 min. The attendant flood reached Swallows, a point on the river 8 miles below the mouth of Beaver Creek, at 11.30 A. M.; Goodnight, 10 miles farther down, at 1.30 P. M.; and Pueblo, an additional 5 miles, at 2.15 P. M. The itinerary of this wave may be scheduled as shown in Table 16.

TABLE 16.

Place.	Flood arrived.	Lapsed time.	Distance traveled.
Reservoir site	9.30 A. M.	.....	.....
Swallows	11.30 A. M.	2 hours	19 miles
Goodnight	1.30 P. M.	2 hours	10 "
Pueblo	2.15 P. M.	0 hours 45 min.	4 "
Total	.....	4 hours 45 min.	33 miles

It is important to note that, at its crest, the flood, as recorded at the Main Street gauge, did not exceed 28 000 sec-ft. at a gauge height of 13 ft., or more than 5 ft. below the 18.14-ft. gauge of overflow point. In all probability if there had been no breaks in the levees from the flood of June 3d, the channel would have carried the flow from the Schaeffer Reservoir. The most important fact, however, is that notwithstanding the reading on the Main Street gauge was 5 ft. below the overflow point, the water was several inches above the floor of the Union Depot, and probably reached a gauge height there of about 18.00 ft., the overflow point at Main Street. This is direct confirmation of a previously mentioned observation to the effect that when the river had fallen to its channel overflow point at Main Street, in the early morning of June 4th, with a rated discharge flow of 45 000 sec-ft., large volumes of water were flowing through other parts of the city from breaks in the levees near the West Fourth Street Viaduct. Although the total volume from the Schaeffer Reservoir was relatively small and effected no serious damage at Pueblo and points farther east, yet, due to the release in the body, the damage inflicted in the valley west of Pueblo was far greater than in the previous flood, and left a real "valley desolate".

Flood Loss.—The authors are to be congratulated in assembling even preliminary figures on this most illusive factor of property loss, and there seems to be no warrant for suggesting change in the amount submitted. The figures are of inestimable value in planning protective or preventative measures and are an index of the justifiable extent to which such measures can be recommended. Doubtless, these amounts, together with the possibility of a future occurrence of a flood of equal or greater magnitude, will be weighed against the cost of assured protection. It is too bad, though, that mention was not made of the most vital factor in the whole matter. More than 150 lives were lost—the exact number can never be known. Thus far, 78 bodies have been recovered. Men might ponder at great length as to the justifiable investment to guard against property loss, but if the people in this part of the Arkansas Valley must return to their industrial pursuits, and it is assumed that they must, there is no warrant for hesitancy. The futility of placing monetary value on a human life should not restrain the engineer as a true conserver from placing personal safety in industry far above all things else.

Estimated Peak Flow and Volume.—The peak flood of the Arkansas River through the City of Pueblo was in all probability about 100 000 sec-ft., as first estimated by Mr. Hosea. This figure will be confirmed or corrected when the investigations now in progress are completed. The channel had a flood capacity of about 40 000 sec-ft., without any margin of safety. Improvements necessary to insure such capacity with a reasonable degree of safety could be effected at nominal expense. It would seem, therefore, that, in considering protective measures involving substantial investment, provision is necessary only for those floods of a greater discharge rate than 40 000 sec-ft. The volume in the Arkansas, passing through the city in excess of a discharge rate of 40 000 sec-ft. could not have been more than 30 000 acre-ft. The Fountain River, flooding a safe channel with a capacity of 25 000 sec-ft., for 12 hours, with a peak discharge of 45 000 sec-ft., would have a volume of about 10 000 acre-ft. without channel provision. In other words, if 30 000 acre-ft. had been held back on the Arkansas for a few hours and 10 000 acre-ft. on the Fountain, no disaster would have occurred at Pueblo on the night of June 3d.

It does not appear that the combined maximum flow of the Arkansas and Fountain of 65 000 sec-ft., together with the accretions of the tributaries east of Pueblo, would work any hardship on the lower valley. Prior to the June flood, a peak flow greater than 40 000 sec-ft. had not passed Pueblo in the Arkansas for a period of 100 years or more, if historical deductions are correct. The average daily discharge for a period of 11 years—1910-20—was 770 sec-ft.

Drainage Area and Run-Off Data.—It is true that the part of the Arkansas Basin between Canon City and Pueblo supplied nearly all the run-off in the flood of June 3d, yet by no means can the drainage basin of 3 047 sq. miles

above Canon City be ignored in considering protective measures. Notwithstanding the fact that the greatest discharge at the Hanging Bridge in the Royal Gorge since the construction of the railroad in 1880 has probably not exceeded 9 000 sec-ft., Grape Creek, which flows into the Arkansas just below the Grand Canyon, has a formidable drainage area of 483 sq. miles and is subject to excessive floods. The railroad branch in the canyon occupied by this stream, extending from Canon City to Silver Cliff, was several times seriously damaged by floods, and, in 1889, after only nine years of operation, was so nearly destroyed that it was permanently abandoned.

Table 17 shows the daily and total precipitation measured by various observers at points in the Fountain and Arkansas Basins during the storms of June 2d-6th, 1921. Attention is directed to a previous error in the Colorado Springs precipitation for June 3d which is corrected herein.

It is inconceivable that the heavy precipitation of Friday evening and night could extend over any considerable area, and equally irrational to apply the averages deduced therefrom over the entire drainage basin of either the Fountain or Lower Arkansas Rivers. An incontrovertible fact of long standing is that by far the greater volume of precipitation in the Colorado Arkansas is the result of violent rain storms. There should be no hesitancy in saying that the basin, especially the lower part, is infested with cloudbursts, for no other nomenclature better fits the observed phenomena. Grouped according to elevation, these stations furnish the results shown in Table 18.

TABLE 18.—AVERAGE INCHES OF RAINFALL, STATIONS ABOVE PUEBLO, COLO., IN 72 HOURS, JUNE 2D-6TH, 1921.

Elevation, in feet.	Number of stations.	Average inches of rainfall, 72 hours.
4 600 to 5 000	6	9.17
5 000 to 6 000	4	6.94
6 000 to 7 000	1	3.77
Above 7 000	6	3.49
Total.....	17	6.41

It will be observed from Table 18 that, for this particular series of storms, the precipitation varies inversely with the altitude, a fact contrary to the commonly accepted law which doubtless will apply only to precipitation from general storms. Even in the mean annual precipitation, there is a slight vagary in this law in the Upper Arkansas Basin. No reason is advanced as to why the probable maximum precipitation in 72 hours should be exactly 140%, rather than any other multiple of the greatest precipitation of record; neither is it clear that the figures for percentage of run-off will apply to this particular region. In the 11 years, 1910-20, the ratio of mean annual run-off to mean annual precipitation for the basin above Canon City was 23%, and 19% for the entiré basin above Pueblo. On the other hand, it is easy to conceive that the ratio from cloudbursts, in some of the tributaries with exces-

sive gradients, might closely approach 100 per cent. Apparently, the law of averages will not apply in this case, except in a very limited manner; rather should the analysis consist in a study of each individual tributary. For example, it is known that Oil Creek, with a drainage area of 416 sq. miles, never floods frequently or excessively, while, in contrast, Rock and Peck Creeks are subject to frequent floods. Hardscrabble has idiosyncrasies well worthy of analysis. Other tributaries have similarly developed certain characteristics, the permanency of which has not yet been assailed. Doubtless, the position of the confining mountain ranges, their altitude, and their relation to each other, as well as to the Great Plains, have a great deal to do with the case.

It may be possible to construct from past records, combined with personal experiences and accumulated data, a synthetic programme of a probable maximum flood at Pueblo. The apparently insurmountable obstacle in this programme will be the occurrence and intensity of cloudbursts, the forecasting of which has thus far baffled all attempts at solution.

Flood Control.—The answer to the problem seems to lie in some scheme of flood-regulating reservoirs. This is by far the safest plan, for, regardless of the magnitude of the flood peak, discharge through the channel will be limited to its capacity. The only further concern will be in ascertaining the volume of maximum flood which it will be necessary to hold back, and this factor is more susceptible of definite determination than the peak flow of any imaginary flood.

Obviously, the channel through the city should be as large as ultimate economy will permit. The larger the city channel, the smaller will be the required detention. This is a distinct advantage in that it will reduce the cost of maintaining reservoir capacity against the deposit of enormous quantities of débris brought down by the torrential flood velocities of the river and its tributaries. On the other hand, the city channel ought to be as small as possible, for, otherwise, property suited for intensified use would be devoted to only occasional service during extraordinary floods. An infrequently used flood channel, many times larger than would be required for normal flow, would constitute waste land in the heart of the city and impose extra burdens on the daily conduct of city affairs. Again, a city channel of maximum flood capacity would be no safeguard to life and property in the valley east of Pueblo, whereas confinement of the river within minimum and permanent limits would permit the cultivation of land otherwise unproductive.

In the interest of conservation, it would seem, therefore, to be necessary first, to determine the size of the channel which the value of property both urban and rural can consistently bear, and weigh this cost with that of reservoirs to supplement the channel in passing the floods. The only unknown quantity in the problem is the volume and peak flow of the possible maximum flood. The suggestion of a rainfall 40% in excess of the two greatest storms on record, distributed over the water-shed according to altitude and running off at assumed rates, is not entirely satisfactory. There is no certainty that the records of the 1894 flood tell the whole story, and it is quite certain that the records used for the 1921 flood do not. Moreover, the altitude distribution

over the whole water-shed of the few available averages and the assumed percentages of run-off do not seem wholly applicable to the Arkansas Basin. Here, the precipitation is spotted, storms are greatly concentrated in area, flood rainfall is extreme in intensity, and run-off is widely variant.

As the concern in the maximum peak discharge is only for the purpose of providing requisite channel capacity without control reservoirs, it may be that the suggestion of 168 000 sec-ft., as crest discharge in the Arkansas, will answer the purpose. However, it is entirely possible, with the same intensity of storms and slightly different distribution over the tributary basins, to have greater peak flows with smaller volumes than even that which occurred on June 3d, 1921. In this phase of the problem, the vital factor is the torrential rains in certain tributaries, which might make their peak discharges coincident at the critical point in the river. The difficulty lies in the local concentration of storms in places where no long-time records have been kept. Similarly, it may be that the figures of 322 000 acre-ft. in the Arkansas River represent the greatest possible volume of flood of a few days' duration, but as the method by which they were deduced is open to question, their reliability is not assured.

As previously mentioned, the present channel of the Arkansas River can and did carry 40 000 sec-ft., and can be made to do so with an adequate margin of safety at nominal expense. Apparently, therefore, the detention reservoir capacity should be computed on this basis. The development of the Rock Canyon site to requisite capacity, even with this promise, may not be sound economy, but it does not yet appear to be impracticable to obtain a part of the detention capacity on some of the tributaries. For instance, Dry, Boggs, and Rock Creeks were the worst offenders in the recent flood. Peck Creek is often and Hardscrabble occasionally the culprit, but this time neither was very unruly. The flood duration on all these streams is very brief. From data collected in the field, the maximum rate of discharge and total volume of flood for the three first-named streams may be approximated as follows:

	Second-feet.	Acre-feet.
Dry Creek	17 000	7 000
Boggs Creek	33 000	13 500
Rock Creek	36 500	15 000

The channels of these streams and the river below their conjunction therewith will carry substantial flows without damage, and apparently reservoirs of adequate capacity for their control would be quite practicable. On investigation other tributaries will doubtless yield even greater promise of advantage.

It is entirely practicable, although somewhat expensive, to remove the railroad tracks and the Bessemer Canal from any reservoir basin at the Rock Creek site. The suggestion of leaving these works within the basin to be subject to occasional submergence as an economic measure is not at all clear. Aside from that incurred by the failure of the Schaeffer Dam, most of the railroad damage west of Pueblo accrued from floods in the tributaries. Any advantage gained by checking main stream velocities within the reservoir limits would doubtless be trifling in contrast to the enormous loss from inundation and subsequent excessive cost of clearing the submerged works from a heavy deposit of detritus.

The topography of the Fountain River is not as favorable as that of the Arkansas for the construction of retarding reservoirs, but the channel through the town is more susceptible of improvement and enlargement. Any reservoir site on the Lower Fountain River, and there seems to be none of any great promise, will be expensive for the installation of control works, and, perhaps, prohibitive in cost per acre-foot capacity. It is also quite likely that the difficulty of securing satisfactory foundations will militate against the adoption of a detention plan.

A consideration of all the phases of the situation indicates preference for the improvement and enlargement of the channel through the city as the best plan. This view is influenced by the probability that after a thorough investigation the peak flow of any future maximum flood will be taken at substantially less than the suggested 110 000 sec-ft. Present information indicates that the probable maximum crest will exceed the 45 000 sec-ft. of June 4th, 1921, by only a small proportion. However, any plan for flood control on the Fountain River must be co-ordinated with plans for controlling the Arkansas River, in order to obtain the desired results in the valley east of Pueblo.

The authors are to be commended most highly for including even a roughly approximate statement of cost for the various plans suggested. This information will doubtless serve the desired purpose of emphasizing the gravity of the entire situation. With still only very meager data at hand, it is impossible to confirm or revise the estimates. Attention is called to a possibility of reducing the amounts very materially after a more mature investigation as to whether the Fountain peak of 45 000 sec-ft. of June 3d and 4th, 1921, was not a probable maximum, or nearly so, and also by basing the Arkansas computations on a channel capacity of 40 000 sec-ft.

The utilization of water accumulated by detention reservoirs for either irrigation or power purposes does not now appear to be entirely practicable. Detention reservoirs must be emptied as speedily as the channel capacity will permit, for in some seasons torrential rains in the water-shed have a pernicious habit of rapid repetition. The storage of large quantities of water to be used slowly could only be accomplished by quickly drawing off the detained volumes into other basins through canals of large dimensions. Still, this feature of the case is a move toward the utmost utilization of natural resources, and it is worthy of some consideration and investigation.

R. G. Hosea,* Esq. (by letter).—Since the Arkansas River flood of June 3d, 1921, two questions frequently asked of the State Engineer's Office, are:

1. What was the peak flow of the flood at Pueblo?

2. What quantity could have been safely carried through Pueblo, in the existing river channel?

The first question is extremely difficult to answer and probably may be estimated more intelligently after a consideration of the second.

Through the main part of Pueblo, the channel of the Arkansas River is approximately 150 ft. wide, between nearly vertical masonry walls 18 ft. high. The State gauging station was located at the Main Street Bridge, where frequent measurements were made at low-water stages by wading and from

* Deputy State Engr., Denver, Colo.

the bridge during high water. On June 2d, at 10.00 A. M., the following measurement was made by Messrs. H. D. Amsley and G. C. Price, State Hydrographers: Gauge height, 4.69 ft.; area, 444 sq. ft.; discharge, 2 417 sec-ft.; and mean velocity, 5.44 ft. per sec.

From 6.00 to 6.20 P. M., on June 3d, these men also made a float measurement by timing with stop-watches logs and drift over a 100-ft. course. This measurement is only a rough approximation, since the river rose 1 ft. (from Gauge 10.6 to Gauge 11.6) during this time, and it was impossible to obtain accurate soundings. The depths, therefore, were computed, using 11.2 ft. as the mean gauge height for the period. The velocities thus obtained were 10 ft. per sec. near the side-walls and 15.2 ft. per sec. in the central part of the channel.

The area computed, using 11.2 ft. as the gauge height (and making an assumption as to the amount of scouring of the channel, as explained later), was 1 505 sq. ft. The mean velocity was 11.8 ft. per sec., based on the following assumptions: Mean velocity = 0.90 of surface velocity; surface velocity for 30 ft. from each wall = 10 ft. per sec.; and surface velocity for 90 ft., central part of channel = 15.2 ft. per sec. This gives a discharge of 17 905 sec-ft.

The channel at the Pueblo Station is subject to scouring during high water and filling again under normal conditions. This condition was particularly apparent before and after the flood of June 3d. A measurement made on June 7th showed: Gauge height, 5.60 ft.; area, 788 sq. ft.; discharge, 6 274 sec-ft.; and mean velocity, 8.0 ft. per sec.

Comparing this measurement with that of June 2d, it is seen that the gauge height was 0.91 ft. higher, corresponding to an increase in area of 0.91×150, or 136.5 sq. ft., while the measured area showed 344 sq. ft. more, leaving an excess difference of 208 sq. ft. caused by scouring. This amounts to an average increase in depth of 1.4 ft. in a channel 150 ft. wide (in one place, the actual increase was slightly more than 3 ft.). In computing the area for the float measurement of June 3d, it was assumed that one-third of this scouring had taken place. A measurement on June 29th, showed: Gauge height, 4.77 ft.; area, 542 sq. ft.; discharge, 2 865 sec-ft.; and mean velocity, 5.38 ft. per sec. This area when compared with that of June 7th, shows that during this time the channel filled an average of 0.8 ft. over the 150-ft. section, and was evidently approaching its condition prior to the flood.

The Main Street Bridge at Pueblo is an old-fashioned Bollman truss, with floor-beams, spaced about 10 ft. apart, extending below the lower chord. Levels taken a few days after the flood showed the following gauge heights: Bench-mark on stone coping (top of channel side-wall), Elevation 4875.19, equals 18.18 ft.; sidewalk of bridge, 18.66 ft.; top of floor-beams, 17.68 ft.; bottom of floor-beams, 14.68 ft.; and bottom of stringers, 16.85 ft. The high-water mark on the City Auditorium, adjacent to the bridge, is 4 681.71, or 6.5 ft. above the top of the channel coping.

It is evident that the channel could not safely carry water over a gauge height of 14.68 ft. and at this elevation it would reach the bottom of the floor-beams. However, as an estimate of what might have been carried in the channel, a gauge height of 16.85 ft. was used as the clearance line of the bottom of

the lower stringers of the bridge. Probably the most accurate determination of the flow at this gauge height may be made from a logarithmic discharge curve, based on previous measurements and on the measurements already referred to, since this will be a straight line and can be accurately extended.

At a gauge height of 16.85 ft., such a curve gives a discharge of 45 000 sec-ft. From this, and the computed area (approximately 2 300 sq. ft.), a velocity of 19.5 ft. per sec. is obtained. Extending a velocity curve is not satisfactory, because of discordant values due to shifts. Such an extension, however, indicates a velocity of about 18 ft. per sec. at a gauge height of 16.85 ft. and a corresponding discharge of 41 400 sec-ft.

As a rough check on these values, on June 29th, 1921, a determination of Kutter's n was made for the river channel from the Victoria Avenue Bridge to the Main Street Bridge, a distance of 768.5 ft. At the Victoria Avenue, Union Avenue, and Main Street Bridges, careful levels were taken to the water surface at nine different points on each section. Using the mean of these nine values as the surface elevation at each section, the following results were obtained:

Victoria Avenue, mean water surface	4 662.61
Union Avenue, " " "	4 662.25
Main Street, " " "	4 661.82
Difference in elevation,	
Victoria Avenue to Main Street	0.79 ft.
Distance	768.5
Slope	$\frac{0.79}{768.5} = 0.001 +$

Careful current-meter measurements were made at Main Street and at Union Avenue, and a careful cross-section was taken at Victoria Avenue. The two meter measurements showed a difference of 3.4% (to be expected in cable measurements), and the mean discharge of 2 865 sec-ft. was used. The height on the Main Street gauge was 4.77 ft.

The "hydraulic elements" of the three sections were as given in Table 19.

TABLE 19.

	Victoria Avenue.	Union Avenue.	Main Street.
Area, in square feet	485.7	488.7	542.1
Perimeter, in feet	155.0	155.0	155.0
Discharge, in second-feet	2 865.0	2 865.0	2 865.0
Mean velocity, in feet per second	5.9	5.75	5.38
Hydraulic radius	3.2	3.2	3.5

The mean section computed from the values given in Table 19, has the following elements: Area, 505.5 sq. ft.; discharge, 2 865 sec-ft.; mean velocity, 5.67 ft. per sec.; wet perimeter, 155; $r = 3.26$; and $s = 0.001$.

Solving for Kutter's C and n, these elements give $C = 99.3$, and $n = 0.0182$. Merriman* gives for Kutter's n:

$n = 0.20$ for canals in very firm gravel.
$n = 0.017$ " rubble masonry.

* "Hydraulics," 1906 Edition, p. 282.

This instance is a canal section with a firm gravel bottom and rubble masonry sides, and, as might be expected, n is intermediate between 0.017 and 0.020.

It is found that, for the float measurement of June 3d, 1921, $C = 126$ and $n = 0.016$, using the following elements: Area, 1 505 sq. ft.; mean velocity, 11.8 ft. per sec.; perimeter, 172.0 ft.; $r = 8.75$; and $s = 0.001$.

This is based on the assumption that the slope remains the same for a much higher gauge height and a much greater discharge, which, in turn, assumes a free outflow below. In view of these assumptions and the uncertainty in the measured velocity, it is probable that the value of $n = 0.016$ should only be taken as an indication that n decreases as the flow increases.

If n does decrease at the rate indicated, for a gauge height of 16.85 ft., it should be about 0.014, in which case: Area, 2 300 sq. ft.; discharge, 37 950 sec-ft.; perimeter, 182.5 ft. (approximate); $r = 12.5$; $s = 0.001$; $n = 0.014$; $C = 147$; and $v = 16.5$ ft. per sec.

In applying three different methods, the three values obtained:

(*a*) 45 000 sec-ft. logarithmic discharge curve
(*b*) 41 400 " " extended velocity curve
(*c*) 37 950 " " Kutter's formula

give a mean discharge of 41 450 sec-ft., or, roughly, 40 000 sec-ft., as the maximum which could pass under the Main Street Bridge.

Peak Flow.—The actual peak flow of the flood of June 3d, 1921, is not known, but an estimate may be made in an intelligent way and thus, perhaps, a figure established within certain reasonable limits. It is not known how much of the excess height (above the top of the river channel) was caused by obstructions at bridges and in the area adjacent to the mouth of the Fountain River. High-water marks show that the river rose about 7 ft. above the stone coping which tops the side-walls of the river channel. If the maximum possible carrying capacity of the channel to the top of the coping is taken as 45 000 sec-ft. and to that is added the quantity which could be carried by an additional 7 ft. in depth (which would be, say, 150 ft. wide by 7 ft. deep by 20 ft. per sec. velocity), a total of 45 000 + 21 000, or 66 000 sec-ft., is obtained. This assumes, of course, an unobstructed flow in a channel 7 ft. deeper than the present one, but takes no account of the water which flowed outside the present channel, through the town.

Since, of course, this condition of unobstructed flow did not and could not exist at this gauge height, it may be contended that this velocity of 20 ft. per sec. did not exist and that, as the water backed up, its velocity was decreased. No account, however, has been taken of the quantity of water passing through the town, and it is probable that this effect must have been more than counterbalanced and that the figure of 66 000 sec-ft. is a minimum estimate of the peak.

On June 19th, 1921, a cross-section of the Arkansas River, at a point above the mouth of Dry Creek at the Denver and Rio Grande Mile Post 120 + 4 082, was surveyed by W. A. Balcom, Division Engineer, of the Denver and Rio

Grande Railroad. From high-water marks, the area of this section was found to be 8 610 sq. ft., wetted perimeter, 751.6 ft., and the slope of the river was 0.0028 for 1 200 ft. above the section and 0.0022 for 877 ft. below it. Using a mean slope of 0.0025 with these figures and a value of $n = 0.035$, Kutter's formula gives a discharge for this section of 99 876 sec-ft. Using $n = 0.04$ (which seems to be a more reasonable value), the discharge becomes 86 100 sec-ft., about 14% less.

To this must be added the flow of Dry Creek. Late Thursday night, June 2d, 1921, a local cloudburst flooded Dry Creek, and judging from reports, it carried more water then than at the time of the "big flood". Therefore, estimates made from water-marks may give figures for this first flood. The first flood, a large part of which came from the cloudburst on Dry Creek, however, was recorded on the automatic gauge at Pueblo, and, apparently, caused a rise of about 20 000 sec-ft. in the river. The second flow in Dry Creek, if assumed as equal to the first, and added to the Arkansas River at the Denver and Rio Grande Section, will give 86 100 + 20 000 = 106 100 sec-ft. as the peak flow at Pueblo. (In this connection, it is interesting to note that the figures for Dry Creek indicate a run-off of nearly 300 sec-ft. per sq. mile, the drainage area of the creek being about 70 sq. miles.)

The following drainage areas tributary to the Arkansas River between Canon City and Pueblo, have been obtained from the United States Topographic Sheets:

South Side:		
Pueblo to Boggs Creek	20	sq. miles
Boggs "	25	" "
Rock "	67	" "
Peck "	46	" "
Rush "	34	" "
Red "	42	" "
Ritchie "	40	" "
Hardscrabble Creek	186	" "
Coal Creek	28	" "
Oak "	72	" "
Chandler Creek	38	" "
Total	598	" "
North Side:		
Dry Creek	71	" "
Turkey "	215	" "
Beaver "	260	" "
Eight-Mile Creek	140	" "
Oil Creek	456	" "
Total	1 142	" "
Fountain Creek	930	" "

Although a drainage area of about 3 000 sq. miles is tributary to the Arkansas above Canon City, it is known that this area did not contribute, appreciably, to the flood, as the automatic gauge on the river at Canon City recorded a maximum flow of about 4 000 sec-ft. It is also known of the areas previously tabulated, that only a few flooded excessively. Fountain Creek is excluded from the discussion for the present, since it joins the Arkansas River below the Pueblo Station.

Water from the greater part of the Turkey Creek drainage was held up by the Teller Reservoir, and that from the Beaver drainage by the Schaeffer Reservoir, until the time of its failure about 10 A. M., on Sunday, June 5th, 1921.

Mr. Wells, Superintendent of the C. F. and I. Company's Arkansas Valley Conduit, who is intimately familiar with the south side of the river and in touch with conditions both through personal observation and reports from his ditch riders, states:

"The flood of June 4th was caused by rain falling east of Rush Creek, which enters the river at Swallows. Very little water came down Rush Creek and there was no water either in Ritchie Gulch or Red Creek. Peck Creek, Rock Creek, and Boggs Creek were the creeks that caused the flood."

This statement is corroborated by the postmasters at Siloam and Wetmore, who state that, although a heavy rain fell in their section, it fell steadily and penetrated into the soil.

The combined drainage areas tributary to the Arkansas River, between Pueblo and Swallows on the south side, aggregate about 150 sq. miles and, including Dry Creek on the north, 220 sq. miles. Even if the entire south side drainage, as far west as Portland, is included, there are only 336 sq. miles (eliminating Turkey Creek and Beaver Creek). If a run-off equal to that of Dry Creek on June 2d, 1921, namely, 300 sec-ft. per sq. mile, is assumed, there would be a combined flow of 100 800 sec-ft.

A rainfall of 12 in. in 24 hours on an area of 1 sq. mile, with complete run-off, is equivalent to 640 acre-ft., or a rate of 320 sec-ft., which is nearly what has been already assumed. Such rainfall is very much higher than any reported during the storm which caused the flood of June 3d, 1921, but it could have occurred over a limited area in the Boggs Flat Section where the storm appears to have been the heaviest. Unfortunately, no accurate records are available from this area.

The authors suggest that protection be provided against a peak flow of 168 000 sec-ft. This is based on the run-off from a storm 40% greater than any recorded, using certain assumptions as to rainfall and run-off; 60% of 168 000 sec-ft. is 100 800 sec-ft. which, again, roughly corroborates the estimate of the peak flow.

The evidence seems to show that the peak flow amounted to approximately 100 000 sec-ft., possibly more, but more likely less, since the assumptions on which this estimate is based, are extremes purposely taken in order to be sure that the figure should be too large rather than too small.

The Fountain Creek flood reached Pueblo sometime after the peak of the Arkansas flood had passed, and its peak was reached at, perhaps, 3.30 A. M.,

Saturday, June 4th, 1921. A preliminary estimate placed this peak at 50 000 sec-ft.

A cross-section opposite the Denver and Rio Grande Mile Post 117, approximately 2 miles above Pueblo, surveyed by its engineers, gives between high-water marks the following: Width = 921 ft.; maximum depth = 9.4 ft.; area = 5 258 sq. ft.; perimeter = 940 ft.; hydraulic radius = 5.6; and slope = 0.0042.

The peak flow of Fountain Creek at this point, calculated by Kutter's formula, with $n = 0.035$, was 46 500 sec-ft., and with $n = 0.040$, 40 100 sec-ft. At that time, there may have been 75 000 sec-ft. in the Arkansas River. This would give a total volume of 120 000 sec-ft. as the combined discharge of the two streams.

Below Pueblo, the largest flood in a tributary stream occurred in the St. Charles River. As this flood was caused by the rain storm which brought about the Arkansas flood, and had a shorter distance to travel, it is likely that its peak reached the main river before that of the main flood. Definite information on this point cannot be secured at this time.

From a cross-section made by Messrs. H. D. Amsley and G. C. Price, the peak flow of the St. Charles is indicated to be about 50 000 sec-ft. If one-half of this flow was coincident with that of the peak in the main river, the combined flow below the St. Charles would be 145 000 sec-ft., to which Chico Creek added its volume.

A cross-section of Chico Creek, taken by Messrs. Amsley and Price, indicates that it carried a little more than 20 000 sec-ft., and the statement of Mr. Edson, Foreman of the North Avondale Milling Company's ranch, fixes the time of the rise in Chico Creek at 4 A. M., June 4th, 1921. This would bring it at about the time of the peak in the Main River at this point, and would give a total of about 165 000 sec-ft.

The Huerfano River did not flood excessively, but, from gauge heights at the Ellis Dam, it is estimated that it contributed from 5 000 to 6 000 sec-ft. Below this point, the tributary streams were not unusually high, although they probably did furnish some excess water. If the sum of the tributaries between the Huerfano and La Junta is estimated as 10 000 sec-ft., the peak at La Junta was 160 000 sec-ft.

At the head of the Fort Lyon Canal, about 3 miles west of La Junta, a cross-section was taken by Messrs. Amsley and Price, and the flow estimated through this section as the peak flood is from 180 000 to 200 000 sec-ft.

At the head of the Amity Canal, near Prowers, certain flood-flow estimates were made by Oscar Hallbeck, Engineer for the Arkansas Valley Sugar Beet and Irrigated Land Company, as shown in Table 20.

The figures given in Table 20 show a peak flow of 170 000 sec-ft. which continued for 3½ hours, with a gradual decline, and a total discharge of, approximately, 200 000 acre-ft. in 24 hours. It is probable that the peak would flatten out on the lower river and that the flow would continue for a longer time, as indicated in the measurements at the Amity Dam.

This effect is still further illustrated by measurements not yet available, taken at Syracuse, Kans. At this point, the river did not overflow its channel, but was confined between the abutments of the bridge, in a channel about 800 ft. wide. Mr. Knapp, State Water Commissioner of Kansas, estimates the peak flood at this point as not more than 50 000 sec-ft. (subject to verification). Evidently, the time of passage of the flood must have been considerably longer, if these figures are correct.

Information now being gathered may show minor discrepancies in some of these figures and will doubtless throw more light on the actual area of origin of the flood, but it is believed that, in the main, the conclusions arrived at are correct within reasonable limits and may be of value in considering plans for future flood protection.

Although the greater part of the damage done was in and around Pueblo, it is evident that great losses occurred in the lower valley, particularly to irrigation structures, and a complete flood-protection plan should consider the lower valley as well as Pueblo.

In the writer's opinion, the adoption of a "conservancy district" law, similar to that of Ohio, should be passed as a first step, in order to provide the machinery for raising money for the construction of flood-prevention works. The costs of the necessary works should be assessed in proportion to the benefits to be derived, against cities, towns, corporations (public and private), and all other interests benefited.

No detailed definite study has been made as yet of the possible plans for flood protection, although various schemes have been suggested. A discussion of these plans without adequate information and reliable estimates of cost will not be attempted at this time.

It is due to Mr. Amsley's diligence and foresight in this connection that any reliable figures have been preserved. The measurements made by him June 2d, 3d, and 7th, 1921, and his subsequent work in establishing gauge heights, embrace all the data on record.

Fig. 21 is a hydrograph showing gauge heights and discharge of the Arkansas River, at Pueblo, from June 1st to 7th, 1921. Since the automatic gauge was lost during the evening of the flood of June 3d, 1921, no strictly accurate gauge heights are available from that time until June 6th, but approximations were obtained in various ways, from reliable statements, water-marks, inspection from a distance, counting the number of stones in the side-walls visible above water level, etc.

This graph should be quite accurate except for the time during the peak of the flood when the river was out of its channel. This time is quite definitely fixed, especially the time of the first overflow and the peak flow. The time when the water in the channel was below the stone coping is fixed from the statements of people who spent the night in City Hall. They agreed that the stone copings lining the channel were visible at daylight above the water.

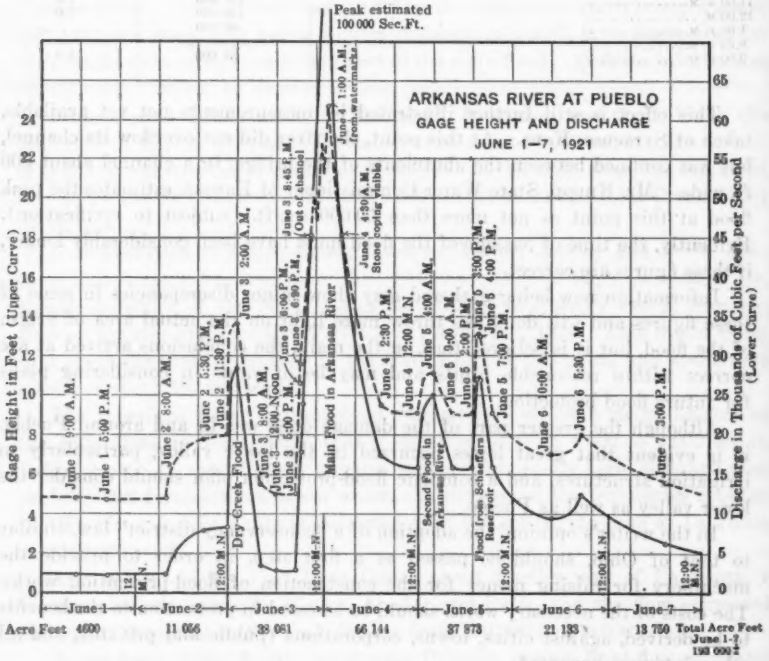

FIG. 21.

An interesting feature of Fig. 21 is the peak representing the flood from the Schaeffer Reservoir which failed about 10.00 A. M., on Sunday. This water reached Pueblo at 2.00 P. M. The total discharge of the river from 2.00 P. M. to midnight, on June 5th, was 15 173 acre-ft. (computed from the diagram). Assuming that the river was falling, from 2.00 P. M. to midnight, at the rate indicated, it would have carried about 11 580 acre-ft. during this time; the difference—3 593 acre-ft.—represents the water from the Schaeffer Dam. The

high-water line capacity of the Schaeffer Reservoir was 3 190 acre-ft., but this was undoubtedly exceeded before the reservoir broke, and this excess between the capacity and the water "accounted for," might be represented by the difference of 400 acre-ft.

The main flood computed from 5.00 P. M., June 3d, to midnight, June 4th, amounted to more than 90 000 acre-ft., or, in round numbers, 100 000 acre-ft. in 19 hours, and is the largest flood in the Arkansas Valley of which there is any record. The total for the week through Pueblo was about 200 000 acre-ft., or more than one-third of the total flow for 1920 at this point.

GEORGE G. ANDERSON,* M. AM. SOC. C. E. (by letter).—The authors have earned the approbation of the members of the Society in presenting the accurate and comprehensive, though concise, statement of the features of the great flood in the Arkansas River in 1921, and the resulting situation in the City of Pueblo and the Arkansas Valley, Colorado. Such approbation is equally due to Mr. Hosea for the able and painstaking manner in which he has presented the facts regarding the flood flows of the river. It was necessary to make clear early that the great volume of the flood, and the extent of the resulting damages, came from entirely natural causes, and in the rehabilitation of the city and of the adjacent territory, serious engineering problems are presented, which call for grave consideration in their solution.

From the testimony of such observers as Mr. Wells (quoted by Mr. Hosea), that the greater part of the run-off, at least on the south side of the river, resulted from the rainfall east of Rush Creek, and in the absence of records of rainfall from a greater number of rain-gauge stations throughout the area covered by the general storm, it may be a warrantable assumption that one-half the volume of 100 000 acre-ft. came from less than 300 sq. miles of drainage area. From information obtained by the writer, while investigating the conditions on Beaver Creek and the upper reaches of Fountain Creek, shortly after the floods, it would appear, however, that intense rainfall occurred on the north side of the river and caused run-off which, undoubtedly, contributed to the flood in some volume.

Mr. Hosea states that the "Beaver Creek drainage was held up by the Schaeffer Reservoir until the time of its failure, about 10 A. M., on Sunday, June 5th, 1921." Of the total Beaver Creek drainage of 260 sq. miles, there are only 136 sq. miles above the Schaeffer Reservoir. On some considerable part of the remainder of 124 sq. miles, there was a very heavy rainfall and a consequent large volume of run-off.

At the Schaeffer Dam a measurement, not by a rain gauge, indicated that 4 in. of rain fell during the night of Friday, June 3d, and the precipitation was stated to have been greater at Beaver Park, about 7 miles southwest. The official record at Florence shows only 0.99 in. of precipitation on June 3d, and only a slight run-off occurred in Eight-Mile Creek during that night. These facts may help to define the approximate western limit of the great storm, although a detail in one element may be pointed out in this connection, and, later, elaborated in a broader aspect of the circumstances as they are now known.

* Cons. Engr., Los Angeles, Calif.

Although the total precipitation for June 3d, at Florence, as given in Table 5, is 0.99 in., it is unlikely that this amount was the total for that day of the rainfall which caused the run-off accumulating in the flood at Pueblo during the night of June 3d and the early morning of June 4th. It is much more likely that the quantity given as the total for that day at Florence was the rainfall up to 6.00 P. M., which hour is the beginning and ending of the Weather Service Bureau's day at various stations in Colorado, for instance, as at Colorado Springs and Lake Moraine, while, at Victor, the day begins and ends at 4.00 P. M. It is noticeable that on the following day, Saturday, June 4th, at Florence the total rainfall is the maximum quantity, 3.31 in. It is probably correct to state that the greater part of this fell during the evening, after 6.00 P. M., and the night of June 3d, and in all probability thus contributed some volume to the flood at Pueblo and, also, to its peak flow.

Although only a slight run-off was observable in Eight-Mile Creek on the night of June 3d, Brush Hollow Creek, the next creek eastward, discharged a very high run-off. Subsequent measurements indicated more than 6 000 cu. ft. per sec. as the peak flow from a drainage area not in excess of 25 sq. miles. The next creek eastward is Beaver Creek which is known to have increased in discharge below the Schaeffer Dam before that structure failed, but all evidences of the volume on that night have been obliterated.

The next creek eastward is Turkey Creek. Although it may be correct to state that the Turkey Creek Reservoir retained the stream flow which occurred above it, there were evidences of quite heavy rainfall on that area, with considerable damage to roads and irrigation ditches. If that heavy rainfall did not extend into the area which the Turkey Creek Reservoir does not intercept, there is indication that the intensity of the storm varied in different localities, which is quite probable. For instance, on the Dry Creek area, the next eastward to Turkey Creek, there is every evidence of intense rainfall and a large run-off.

From the foregoing comments, the writer is of the opinion that, although the greater volume of the Arkansas River flood came from the south side of that stream, and largely east of Hardscrabble Creek, considerable volumes were added from streams on the north side, and that the tributary area of these streams cannot be wholly disregarded in these considerations.

At the Schaeffer Reservoir the heavy rainfall did not commence until about 7.30 P. M., on June 3d, and the consequent run-off may not have reached Pueblo at the time of peak flow, but, undoubtedly, it did add something to the total volume. The flow of Beaver Creek at and below the Schaeffer Dam did not exceed 90 cu. ft. per sec. until 4.00 A. M., on June 4th, when the water surface of the reservoir reached the spillway level.

The writer is of opinion that the statement, "in the two largest storms [of the Arkansas Valley], namely, those of May, 1894, and June, 1921, the average rainfall increases quite uniformly with the elevation of the drainage area", is apt to be misleading, and to require revision in its application to the storm of June, 1921.

As has been stated, the rainfall at the Schaeffer Dam, on Beaver Creek, at an elevation of 5 700 ft., during the night of Friday, June 3d, was about 4 in.

The rainfall, at Victor (elevation, 9 775 ft.), from June 3d, 4.00 P. M., to June 4th, 4.00 P. M., was 2.08 in. Victor is on the western slope of Pike's Peak, while Lake Moraine, at an elevation of 10 200 ft., and Colorado Springs, at an elevation of 6 500 ft., are on the eastern slope and in the Fountain Creek drainage. At the two latter points, the precipitation is given, as recorded in Tables 4 and 5, from 6.00 P. M. of one day to 6.00 P. M. of the next. Table 21 shows the comparative rainfall, in inches, at these points.

TABLE 21.

Date.	Victor.	Lake Moraine.	Colorado Springs.
June 3, 1921	0.03	0.65	5.00
June 4, "	2.08	3.68	4.40
June 5, "	1.55	1.40	1.26
June 6, "	0.37	0.18	0.42
June 7, "	0.01	0.00	0.01
Total	4.04	5.91	11.09

At these three stations, the total rainfall for five days shows that the lower elevation actually had more than twice as much precipitation as the average of the higher elevations. By analyzing the daily quantities, keeping in mind the different hour to which the report refers, the record shows that prior to 4.00 P. M., on June 3d, 0.03 in. of rain fell at Victor, prior to 6.00 P. M., 0.65 in. fell at Lake Moraine, and prior to 6.00 P. M., 5.00 in. fell at Colorado Springs.

The detailed record at Colorado Springs is much more illuminating as to the character of the storm, and, between rainfall and altitude, to the relation for this particular storm:

	Rainfall, in inches.
June 3d, 1921, 3.30 P. M. to 6 P. M.	5.00
June 3d, " 6 P. M. to June 4th, 2 A. M.	4.20
June 4th, " 2 A. M. to 6 P. M.	0.20
June 4th, " 6 P. M. to June 5th, 6 P. M.	1.26
June 5th, " 6 P. M. to June 6th, 6 P. M.	0.42
June 6th, " 6 P. M. to June 7th, 6 P. M.	0.01
Total	11.09

The total rainfall of 9.2 in. at Colorado Springs from 3.30 P. M., June 3d, to 2.00 A. M., June 4th, is comparable with the rainfall of 2.08 in. reported at Victor for June 4th, which really occurred after 4.00 P. M., on June 3d, and probably continued, as at Colorado Springs, until the early morning of June 4th. A similar comparison applies to Lake Moraine, with the alteration that the daily periods are parallel as previously given.

These three Weather Bureau Stations are fairly comparable, for, apart from being the only stations in the path of that particular storm, they are situated, relatively, in the general line followed by the storm of June 3d,

which apparently was almost directly at right angles to the front line of the mountains, with a northeast tendency. Generally speaking, this is a characteristic of these summer storms on the Colorado Plateau.

This actual reversal of rainfall increasing with altitude is not unusual in storms of this character, locally and colloquially called "cloudbursts", since this storm which caused the Pueblo flood, was on an unusual and exaggerated scale. As shown in Table 5, it is traceable, with varying intensity of rainfall, along the eastern slope of the Rockies, almost entirely throughout Colorado, with some favored localities excepted, as, for instance, Trinidad, and well into New Mexico, as far south as Albuquerque, on that night of June 3d.

Such storms are usual during the summer months, and although they originate within the mountains, ordinarily at not excessive elevations, and cause some precipitation inside the front range, the greater part of the rainfall, as in this case, ordinarily occurs on the high plateaus or plains areas. There are those who declare that "cloudbursts" do not occur above an elevation of 9 000 ft.

Under such conditions, it does not seem to the writer that any sound deductions can be made from "average" rainfalls, say, at elevations of from 6 000 to 12 000 ft. For the purpose of establishing merely the relation between rainfall and elevation, it would seem that the method used in Table 6 and the averages derived therefrom are misleading. Considering the column for June, 1921, it is noticeable that the fourth group, 6 000 to 12 000 ft., includes Colorado Springs, Calhan, and Monument, all of which are stations outside the mountains proper and on the plateau or plains area. This group includes Cuchara Camps, with a rainfall of only 1.10 in. Cuchara Camps is in the mountains, at an elevation of about 9 000 ft., and near the head-waters of the Huerfano, but outside the belt of this particular storm. The Huerfano contributed only a small volume to the flood-waters of the Arkansas River, east of and below Pueblo.

The average rainfall was 6.29 in. at the typical plateau stations in that fourth group, Colorado Springs, Monument, and Calhan, and for the typical mountain stations, Victor and Lake Moraine. These stations are close to one another and were in the general path of the storm. The first group of three lie outside the mountains, and the second group well inside the mountain area. Comparing the plateau stations, there is:

	Elevation.	Rainfall.
Colorado Springs	6 000 ft.	10.66 in.
Monument	7 000 ft.	3.72 "
Calhan	6 500 ft.	4.48 "

In the third group, if Trinidad, plainly outside the belt of the intense storm, with a rainfall of 1.05 in., is eliminated, the average rainfall at Canon City and Florence is 5.08 in., which is slightly more than that of Victor and Lake Moraine, 4 000 ft. higher.

In the second group, at an elevation of from 4 000 to 5 000 ft., Pueblo with 4.21 in. of rainfall in 72 hours, is the only station which should properly be

compared. Ordway, Two Buttes, and Rocky Ford were certainly outside the limit of the storm.

In the first group the stations, Lamar and Los Animas, were also outside the storm belt.

Another set of four groups could thus be set up, as follows:

	Elevation.	Rainfall.
Pueblo	4 000 to 5 000 ft.	4.21 in.
Canon City, Florence	5 000 to 6 000 ft.	5.08 "
Colorado Springs, Calhan, Monument	6 000 to 7 000 ft.	6.29 "
Victor, Lake Moraine	10 000 ft.	4.86 "
Average		6.81 in.

The probable relation of rainfall to elevation in such storms is thus more clearly indicated, and the fact is revealed that, at the lowest elevation, Pueblo, the rainfall was only slightly less than at almost the summit of the drainage area. The much more significant feature is that directly within the path of the storm, the average rainfall from various typical stations from which conclusions might be made, just as fairly, if not more accurately, by way of forecast of the results in any recurrence, is more than twice that which the authors find and on which they base some important conclusions.

The official record of precipitation at Colorado Springs shows the maximum of any station within the storm area, and is the maximum rainfall recorded at any station in the period of 30 years. It is possible and indeed probable that rainfall as intense as the 9.2-in. rain, which fell at Colorado Springs during the 10½ hours, from 3.30 P. M., June 3d, to 2.00 A. M., June 4th, occurred west of Pueblo, in some considerable portion of the Arkansas River area, which district is assumed to have yielded the greater part of its volume to the flood. The absence of a sufficient number of well placed rain-gauge stations within the areas subject to these torrential summer storms has never been so well illustrated as on this occasion. If records had been available from a large number of such stations during this particular storm, much more really satisfactory deductions could have been made in place of the estimates, more or less dependable, than can now be arrived at, on the most conservative basis.

The consequent defects are apparent in the tabulation of assumed percentages of run-off, which, to the writer, appear to be unreliable largely because they again are based on the difference in elevation, rather than on the rainfall that did occur at each elevation and the conditions affecting run-off that prevailed at the time of the storm. It would seem, for instance, that a rainfall of 9.2 in. in 10½ hours at Colorado Springs, more than 5 in. of which occurred in 2½ hours, would have resulted in a greater percentage of run-off than from 3.68 in. at Lake Moraine in the same time. From personal observation in many such "cloudbursts"—not of the extreme intensity of this particular storm—it has frequently appeared to the writer that the run-off was almost complete and immediate. It would also appear that above an

elevation of 7 000 ft., with less rainfall within relatively the same period, the run-off would be less than at the lower elevations. On this occasion, in the region of Victor and Lake Moraine, the precipitation above an elevation of about 10 500 ft. was in the form of snow, and, in one instance at that elevation, the run-off from about 10 sq. miles of drainage area did not exceed 50 acre-ft. per day for 3 days after the storm, while the average precipitation, as previously stated, was 4.86 in.

It may be that because "probably one-half this volume [100 000 acre-ft., which passed Pueblo] came from less than 300 sq. miles of drainage area between Hardscrabble Creek and Pueblo, * * * the storm which caused the flood was far from a maximum". It was a maximum, so far as flood volume of the Arkansas River passing Pueblo during more than 30 years is concerned, and so far as intensity of rainfall in adjacent territory, as at Colorado Springs, is concerned. A greater rainfall was recorded at Canon City during the storm of 1894—5.06 in. as compared with 3.40 in. in 1921. Unfortunately, that is the only station in the Arkansas Valley above Pueblo, at which comparison may be made.

Assuming the accuracy of the judgment that 50 000 acre-ft. came from 300 sq. miles, an equally intense rainfall with an equally great percentage of run-off from 1 000 sq. miles would result in a flood of more than 166 000 acre-ft., not three times the volume of the recent flood. It is conceivable, however, that a rainfall of an intensity equal to that at Colorado Springs (elevation 6 000 ft., 9.2 in. in 10½ hours) could occur over all the drainage area in the Arkansas Valley above Pueblo and below Canon City, all of it below an elevation of 6 000 ft., and from 1 740 sq. miles, in place of 1 000 sq. miles, produce a flood equal to or greater in relative volume than that yielded from 300 sq. miles on June 3d, which would approach a volume "three times that of the recent flood".

Under such conditions, with a total run-off of more than 300 000 acre-ft., it may be reasonable to expect a peak flow of 168 000 sec-ft. in the Arkansas River at Pueblo, and it may be essential to provide for that volume, since it is only 68% in excess of the recent flood, although that is the maximum discharge of record in a period of more than 30 years, following a precipitation which is also the maximum in the same period, with the single exception of the record at Canon City.

The results anticipated from the Fountain Creek drainage area, following on a similar study, are not equally convincing, however. The flood of June 3d in Fountain Creek, at Pueblo, showed a total volume of 50 000 acre-ft. and a peak flow of 50 000 sec-ft., both of which are, apparently, the maximum of which there is any record.

From the whole drainage area of 930 sq. miles, the total discharge of 50 000 acre-ft. is equivalent to an average run-off of practically 1 in. Approximately, one-half of that area is below an elevation of 6 000 ft., and the greatest rainfall occurred at Colorado Springs, practically at that elevation. Therefore, on the basis of the authors' tabulation of assumed percentage of run-off—55%—the volume of the flood would have been due to an average rainfall of 1.8 in. There are four rain-gauge stations within the Fountain Creek area,

Lake Moraine, Monument, Colorado Springs, and Pueblo, and the rainfall at these stations, on the night of June 3d-4th, as nearly as it may be established from the reports, was:

Lake Moraine	3.68 in.
Monument	2.90 "
Colorado Springs	9.20 "
Pueblo	3.09 "
Average	4.72 in.

In order to produce a flood of 164 000 acre-ft., on the basis of a run-off of 55%, the average rainfall would have to be in excess of 6 in. Although such anticipated flood might be possible, it does not seem to be probable, in view of the facts that the recent flood in Fountain Creek at Pueblo was a maximum alike in total volume and peak flow, as was the rainfall at Colorado Springs and other stations, with the single exception of Lake Moraine. Such anticipation, at any rate, cannot very well be based on the related data in the recent experience.

As an incidental item in connection with these estimates or forecasts, it may be noted that, on the same basis, the area of approximately 183 sq. miles between the site of the suggested detention reservoir on Rock Creek and Pueblo, might produce a flood greater in peak flow than the capacity of the channel within the levees, which existed in Pueblo prior to June 3d, 1921.

It may be proper, and permissible, to bear testimony to the accuracy of some of the detailed statements made by the authors and by Mr. Hosea. At the time of original construction in 1910, the capacity of the Schaeffer Reservoir, at the spillway level, was approximately, 3 190 acre-ft. Some silting had occurred in the basin, but reduction from that cause was offset by the storage above the spillway level which had occurred prior to the failure. For 12 hours or more preceding the failure on Sunday morning, June 5th, the discharge of Beaver Creek had ranged from 1 500 to 4 000 sec-ft., or more.

The writer passed through the Lower Arkansas Valley, below La Junta, on the morning of June 4th, finding the contributions to the river flow from tributary streams generally as presented. There was some flood flow in Timpas Creek, immediately west of La Junta, estimated at about 1 000 sec-ft., and that was probably all diverted before its junction with the Arkansas River.

In their consideration of "Reconstruction and Flood Control", the authors, very properly, have not attempted to do more than give a general outline of possible alternative and combined methods of improvement that would prevent similar damage in the future, and only in such general terms will comments thereon be submitted.

It would seem to be inevitable, and it certainly would be desirable, to combine any reconstruction work in the City of Pueblo with necessary plans for some improvement of the conditions along the Arkansas River below Pueblo, where very great damage was sustained by irrigation works. The interests of the city and the adjacent farming district are so interdependent that some plan incorporating improvement of mutual benefit should be devised, if at all

possible. The authors indicate the necessity of some such co-operative plan, indeed, in the remark that

"* * * the enlargement of the channel through Pueblo in order to carry the peak flow of the river would not benefit property interests in the valley below; in fact, it might have the effect of slightly increasing the flood peaks in the lower river."

In view of this statement, and for other reasons readily apparent, the suggestion made by Mr. Hosea that the creation of a conservancy district, as the first step toward the rectification of existing damages and the prevention of a recurrence in the future, is probably the best course to be pursued in consideration of all the interests affected. It is also probable that some combined method of flood detention storage and channel enlargement will prove the only effective means.

The location of a storage reservoir or reservoirs of adequate capacity, would be confined, undoubtedly, to the channel of the streams. It is improbable that any site of sufficient capacity can be found at reasonable cost on tributary streams, while experience in the recent flood indicates without doubt that the great volume of the flood occurs outside the front range, or foot-hills, of the mountains. As pointed out by the authors, the only known available site, on the Arkansas River at Rock Creek Canyon, has distinct limitations, and these limitations are not entirely confined to the feature of the development of adequate capacity. Although the authors' studies show a required capacity of 210 000 acre-ft., it may be concluded that 100 000 acre-ft. is the economic limit, and even that is curtailed by practical considerations which seriously affect its possible advantages.

Two important railroads, the Denver and Rio Grande and the Santa Fe, are located in what would become the basin of the reservoir. Their removal to other locations is inevitable, and may occasion considerable physical difficulty. It is not conceivable that the railroad companies would consent to leave the tracks where they are, although the authors suggest that in the remarks that "only the most unusual floods would submerge the railroads * * * by storing water in the reservoir" and "the effect of submergence in comparatively quiet water might cause less damage than the high velocities under present conditions". It may be definitely concluded that practical railroad managers would not consent to assume such chances.

It may be anticipated, also, that the residents in the lower sections of the City of Pueblo and the irrigation interests in the Lower Arkansas Valley will not readily accept a proposal to construct, by a high dam in the channel of the stream, a reservoir of large capacity in such location as would seem to imply a continuing menace to life and property. Such an attitude would merely be the reaction from recent experiences. When it was overcome another attitude, probably as important, would develop in the probable desire of the irrigation interests to utilize the reservoirs for irrigation purposes for "hold-over storage". The authors have touched briefly on this in their concluding remarks, in which it is stated that "it is evident that the supply for additional irrigation development is very limited". Thorough investigation of the stream flow of the Arkansas River and appropriations for storage supply would show,

it may be surmised, that the available supply is now well nigh exhausted by "live rights" attached to projects of capacity, except under such abnormal conditions as those which prevailed on June 3d-4th. Any effort to develop "hold-over storage" in a flood-detention reservoir would probably further complicate the distribution of the stream flow among the present water consumers. Even though it may be true that the available flow is now exhausted by the claims of such prior appropriators, there is also the possibility that the water impounded in the detention reservoir, under the "hold-over storage" plea, might seriously lessen its capacity for its main purpose of flood detention.

The authors give no encouragement to the proposition that such a detention reservoir be used as storage for part of the domestic supply for the City of Pueblo, for the reason that the basin would soon fill with silt. To that perhaps could be added the inadvisability of depending on Arkansas River water, as a source of water supply, under all conditions, if in no other respect than that of purity.

The greatest reliance for future protection in Pueblo will undoubtedly be placed on channels of adequate capacity throughout the city. It would also be desirable to raise street and other grades as much as possible. The most superficial study of the street profile in relation to the top of the levees along the river and of the contours in the flooded district, is sufficient to indicate that if life and property is to be reasonably free from undue hazard, in addition to ample channel capacity in the future, there is entailed a distinct elevation of street and property grades, with all that these changes will involve.

ROBERT FOLLANSBEE,* M. AM. SOC. C. E., and E. E. JONES,† ESQ. (by letter).—The U. S. Geological Survey has recently completed an investigation of the Arkansas River flood for the purpose of publishing a water supply paper on its hydrologic features. The field work was performed by one of the writers, Mr. Jones, and the office studies and report were prepared by Mr. Follansbee. The following discussion is based on this investigation.

The small areas of intense rainfall and the rapid rise of the river at Pueblo, and almost as rapid fall, were the remarkable features of the Arkansas River flood of June, 1921. Unfortunately, no regular records are available for the areas of heaviest rainfall and an idea of the precipitation can be gathered only from statements of local residents of those areas. A summary of such statements obtained by personal interviews is given in Table 22.

The rain of June 3d began about 1 P. M. in the foot-hills north of the valley. By 3 P. M., it had spread over the upper and middle parts of the valley and between 5 and 7 P. M., had reached the lower end near Pueblo. The hardest rain, on Eight-Mile, Rush, and Rock Creeks, occurred between 3 P. M. and 4 P. M., while near Pueblo it did not occur until 10 or 11 P. M. The rain continued with intermissions until sometime after midnight.

For the 48 hours ending on the afternoon of June 4th, the Weather Bureau records indicate that the general rainfall in the Arkansas drainage basin

* Dist. Engr., U. S. Geological Survey, Denver, Colo.
† Denver, Colo.

between Canon City and Pueblo had been from 3 to 5 in., being heaviest in the northern part of the area near Pike's Peak.*

Two principal areas of intense rainfall are indicated from the statements of local residents and the maximum discharges of the tributary streams. The larger area extended from a point a few miles east of Wigwam, near the southern boundary of El Paso County, to the top of the Wet Mountains near Beulah, a distance of 45 miles, and from a point a short distance above the mouth of Rush Creek nearly to Pueblo, a distance of 15 miles. The smaller area, covering the southern slope of the Pike's Peak uplift which forms the northern part of the valley, extended from a point above the Skaguay Reservoir to a point 3 or 4 miles south of the river, a distance of 25 miles, and from Oil Creek to Beaver Creek, a distance of 11 miles. The combined areas cover about 700 sq. miles.

An investigation was made of the tributary streams between Canon City and St. Charles River, a few miles below Pueblo, to determine the maximum discharge of each stream and the approximate time of the discharge. In addition, the maximum discharge of the Arkansas at Pueblo was estimated. The work began on July 6th, 1921, and the high-water marks left by the flood in the various streams could still be readily detected.

The method used was to select on each tributary stream a portion as near the mouth as possible where the maximum discharge had been confined to the channel, and where the channel was sufficiently straight to eliminate as far as possible the effect of the water piling up on the outer side of bends. Cross-sections were selected at the upper, middle, and lower end in each part of stream measured, and stakes were set at the high-water line on each side of the channel. Beginning at the up-stream end, a careful level line was run around the six stakes, closing on the initial stake. Distances on each side between stakes were measured along the high-water line. Between each pair of stakes on opposite sides of the channel the cross-section was carefully measured. Owing to the effect of bends in the channel, the difference in elevation between adjacent cross-sections was not the same, nor was the distance along the high-water line the same. Both distances and differences in elevation between adjacent cross-sections on opposite sides of the channel were averaged to determine the slope between them.

Each cross-section was plotted on a large scale and the area determined by a planimeter. The discharge between the upper and middle sections, and the middle and lower sections was computed by Kutter's formula, using the average area of the two sections. The discharge through all three sections was also computed, using the total slope and the average of the hydraulic factors for all sections. Where the difference in area between the upper and lower cross-sections made a marked difference in the velocity through each section, a correction for velocity of approach was applied to the slope between them. Although the conditions of flow were not the same for all sections, the main

* An investigation of the Colorado Springs records indicates that an error was made in measuring the rainfall at that point, the original figures being 2¼ times too great. As corrected, the rainfall from June 2d to June 6th, was 5.18 in., which agrees closely with 5.91 in. at Lake Moraine and 4.03 in. at Victor, both near-by stations.

TABLE 22.

Location.	Statement regarding rainfall.	Duration of Rainfall: Began.	Ended.
North of Arkansas River.			
Dry Creek near mouth	Cloudburst	4 P. M.	
Dry Creek, Sec. 26, T. 20 N., R. 65 W	Hardest at 10 P. M.	7.30 P. M.

* Forty-eight square miles is the area of Turkey Creek water-shed below the Teller Reservoir, as little or no water passed the dam during the period of maximum discharge of the creek.

† The discharge given for Beaver Creek is the maximum due to the storm which occurred more than 24 hours before the failure of the Schaeffer Reservoir (9 miles above the mouth of Beaver Creek). At the time of the maximum natural discharge of Beaver Creek, the quantity passing the spillway and waste-gates of Schaeffer Reservoir was computed to be 3 100 sec-ft. To this was added the drainage to Beaver Creek from 68.5 sq. miles between the dam and the mouth. The maximum discharge of Red Creek, the chief tributary, was found to be 4 490 sec-ft., or 93 sec-ft. per sq. mile. Applying this unit run-off to the entire additional drainage area gives a run-off of 6 370 sec-ft., which added to the 3 100 sec-ft. passing the dam, gives a total maximum natural discharge of 9 470 sec-ft. for Beaver Creek at its mouth.

A study of each tributary showed that the first flood crests to reach Pueblo were those from Boggs, Peck, Rush, and Red Creeks, and Fred Rohr and Ritchie Gulches, all within a distance of 15 miles, and that the time of their arrival was between 7 P. M. and 8 P. M. Although the heavy rains continued during the afternoon and evening and a considerable volume of water entered the river, no more flood crests reached Pueblo until late in the evening. From 10 P. M. until midnight, the floods from the tributaries near Pueblo, which were the streams having the greatest flood discharge, reached the city. At the same time the flood crests from the most distant tributaries arrived, which caused the rapid rise in the river at that time. The period of intense rainfall was so short and the slopes of the tributary streams so steep that the period of

crest discharge was short. This is shown by the rapidity with which the river fell after reaching its peak.

The maximum discharge at Pueblo was determined by measuring the high-water cross-section and slope at a point just west of Pueblo and above Dry Creek. The discharge was found to be 83 500 sec-ft. (using $n = 0.030$), and the discharge of Dry Creek at the time of the maximum stage of the Arkansas was estimated as 19 500 sec-ft., or a total of 103 000 sec-ft. as the peak flow of the river at Pueblo. From a hydrograph of the river at that place, based on records compiled by engineers of the Denver and Rio Grande Western Railroad Company and data used by the authors, the total discharge at Pueblo from 8 A. M., June 2d, to midnight of June 5th, was found to be 145 000 acre-ft. Of this quantity, 90 000 acre-ft. was the total flow from noon of June 3d to midnight of June 4th.

The nearness to Pueblo of the areas of intense precipitation, and the fact that the flood crests from the streams nearest Pueblo arrived at the same time as the crests from the more distant tributaries, combined with their unprecedented unit run-offs, made a condition that could only result in a flood of great magnitude.

The maximum discharge of the flood of 1894 was only 40% of the maximum of the recent flood and was caused by rains extending over the entire drainage basin. At the time of the 1894 flood, the *Rocky Mountain News* recorded that heavy precipitation on May 30th and May 31st extended over the Arkansas drainage basin, in the form of snow at the higher elevations—notably Pike's Peak and the mountains in the upper end of the basin near Leadville. On the morning of May 30th, Salida reported that rain had fallen continuously for 36 hours and probably would continue during the night. The storm at that point, for duration and volume, exceeded anything in the memory of the oldest inhabitant. Table 4 shows that at the regular rainfall stations the storm of 1894 was more severe than that of June, 1921, and yet with a storm more widespread and of greater general precipitation, the maximum discharge of the river was less than one-half that of the recent flood. During the storm of 1894, small areas of intense precipitation were apparently absent. The important part played by these small areas so near Pueblo outweighs any general deductions which may be drawn from the relation of elevation to rainfall, in its effect on possible floods in the Arkansas River.

Paper No. 1481

RAINFALL AND RUN-OFF STUDIES*

By C. E. Grunsky,† M. Am. Soc. C. E.

With Discussion by Messrs. Dana M. Wood, C. F. Marvin, Rudolph Hering, Olin H. Landreth, Thaddeus Merriman, R. A. Hill, Kenneth Allen, L. Standish Hall, H. V. Hinckley, Walter E. Jessup, E. W. Clarke, W. W. Horner, and C. E. Grunsky.

Synopsis

In California it has been necessary, by force of circumstances, to use rainfall records to a very great extent when approximating the water production of water-sheds. There has been made in that State, therefore, perhaps more than anywhere else in the United States, a study of rainfall and of the relation between rainfall and run-off. As early as 1884, the writer, then Chief Assistant State Engineer, began the study of rain distribution throughout California and prepared for the State Engineer Department a rainfall map (published by the State, but now out of print) based on about 200 rain-station records. All these records were expanded to a common 14-year period (1870 to 1884), for which period the greatest number of complete station records were available. A method of combining station records, after first expressing the rainfall of the climatic year in percentage of the normal annual rainfall, and a method of extending short-term records to long periods, are explained in this paper.

Data are presented to show the range of precipitation in climatic years in the central parts of California, and also the frequency of climatic years with various amounts of precipitation. The difference is pointed out between the normal run-off from any water-shed and the probable run-off that is to be expected in a single season in which the rainfall is normal. The effect of altitude on the intensity of rainfall and on the run-off is discussed, and it is shown that the lower temperature at high altitudes diminishes evaporation and, consequently, increases run-off.

* Presented at the meeting of October 5th, 1921.

† Cons. Engr., San Francisco, Calif.

Formulas are also presented for the calculation of maximum storm-water flow from small and from large areas after the maximum rain intensity for various time-periods has been ascertained. A brief reference to evaporation is made, and a table (Table 9) and a formula (Equation (48)) are presented for estimating the evaporation from known mean monthly temperatures.

The deduced formulas are:

Rain intensity:

$$I = \frac{C}{\sqrt{t}} \text{ in. per hour} \quad \ldots\ldots (1)$$

Maximum rainfall in 1 hour:

$$R = 0.129\ C \text{ in} \quad \ldots\ldots (2)$$

Maximum urban storm-water flow:

$$d_m = 0.645\ a\ I \text{ sec-ft. per acre} \quad \ldots\ldots (17)$$

or,

$$d_m = \frac{5aR}{\sqrt{t}} \text{ sec-ft. per acre} \quad \ldots\ldots (19)$$

Maximum stream flow from large areas:

$$d'_m = 413\ a\ I \text{ sec-ft. per sq. mile} \quad \ldots\ldots (23)$$

or,

$$d'_m = \frac{3\ 200aR}{\sqrt{t}} \text{ sec-ft. per sq. mile} \quad \ldots\ldots (24)$$

$$a = \frac{60}{60 + c\sqrt[3]{t}} \quad \ldots\ldots (29)$$

$$d'_m = \frac{25\ 000\ I}{60 + c\ t^{0.33}} \text{ sec-ft. per sq. mile} \quad \ldots\ldots (30)$$

or,

$$d'_m = \frac{190\ 000\ R}{60\ t^{0.5} + c\ t^{0.83}} \text{ sec-ft. per sq. mile} \quad \ldots\ldots (31)$$

or, fairly approximate:

$$d'_m = \frac{C'\ R}{t^x} \text{ sec-ft. per sq. mile} \quad \ldots\ldots (34)$$

In the foregoing formulas make:

$c = 0.5$ for impervious areas;
$c = 5.0$ for mountainous areas;
$c = 20.0$ for rolling country;
$c = 50.0$ for flat country;
$c = 250.0$ for sandy regions;

$C'' = 3\,500$ and $x = 0.5$ for impervious areas;
$C'' = 3\,300$ and $x = 0.6$ for mountainous areas;
$C'' = 3\,000$ and $x = 0.7$ for rolling country;
$C'' = 2\,100$ and $x = 0.75$ for flat country;
$C'' = 600$ and $x = 0.8$ for sandy regions.

THE WET SEASON IN CALIFORNIA.

As the season advances and the fall months pass, the remark is heard on all sides, "I wonder what kind of a winter we are going to have." This implies,

referring now to the Pacific Slope, and more particularly to California, a desire to know whether the winter will be "wet" or "dry"—a wet winter being one in which the rain and snow materially exceed the normal and a dry winter one in which the precipitation is materially below the normal. To those who are not familiar with the climate of the Pacific Coast, it is necessary to explain that this region is not subject to thunder-storms during the spring and summer and that, in consequence, there is very little rain in the six months from May 1st to November 1st. About 90% of the seasonal rain falls in the other six months, with precipitation at its maximum in midwinter.

On the Atlantic Coast, the rainfall is distributed more uniformly throughout the twelve months of the year, the maximum occurring usually in the spring or midsummer months, and there is a corresponding difference in the behavior of the streams which are the recipients of the run-off resulting from rain or melting snow.

It should be recalled in this connection that many of the Western streams —referring to streams which are not fed, in large measure, from underground sources or by the melting of high altitude snowdrifts—go dry, or almost dry, during the summer and fall, although they may have a large flow in the winter and spring. Their seasonal flow, that is, their flow from some time in the fall, say, from October 1st to the end of the following September, is to be ascribed to the rainfall of the climatic or seasonal year. By climatic or seasonal year, the writer refers to the twelve months from some date about the middle or end of one, to the same date of the next, summer season. By common consent the rain-year of the Pacific Slope has come to be considered as beginning with July. This is proper, because the rain which falls in July and August is generally trifling in quantity and is negligible in its effect on run-off, while any rain in September should be counted as affecting the stream flow in the run-off year beginning about the end of that month. For Western conditions, the necessity is thus apparent of discussing the seasonal-annual, or the climatic-year, rainfall in its relation to seasonal annual run-off. A comparison of the calendar-year stream flow with the calendar-year rainfall would be meaningless. Likewise, any comparison of rainfall in one calendar year with that in another calendar year is not only valueless, but absurd.

To illustrate this point, let five consecutive climatic years, Fig. 1, be considered, in the first of which the rainfall has been normal; in the second year, 50% of normal; in the third, 200%; in the fourth, 50%; and in the fifth, again normal. For such seasons, the corresponding stream flow may have been about 100% of normal in the first and fifth seasonal periods of twelve months; about 25% of normal in the second and fourth periods; and 400% in the third period. By calendar years, assuming like quantities of rain each winter before and after January 1st, one-half of the rainfall of the first seasonal year would be combined with one-half of that of the second year, and so on, and, for four calendar years, the rainfall record would appear as 75% of the normal for two years thereof and 125% of normal for the other two. These figures, showing a departure of 25% from normal, instead of 50 to 100%, as in the case of the climatic years, do not give a correct idea of what has happened, and they cannot be brought into any instructive relation to the resulting run-off from the water-shed on which this rain fell. Any deductions attempted

from them pertaining to the relation between annual run-off and rainfall would be misleading.

It is to be hoped that some day this fact will be recognized by the U. S. Weather Bureau, and that the publication of calendar-year precipitation totals will be discontinued with a substitution therefor of climatic-year totals. On the Atlantic Slope, non-compliance with this desirable subdivision of the calendar year has not resulted in the same degree of inconvenience to the engineer as in the West where the need therefor is more obvious. If uniformity of publication is desired, the requirements of the West in this important matter should control. In this respect the Weather Bureau should follow the example of the Water Resources Branch of the U. S. Geological Survey which has long adopted a run-off year beginning with October 1st, a time when throughout the country the streams are ordinarily at their low stages. The climatic year for which meteorological data are desired, should begin at any convenient time between July 1st and October 1st. As run-off due to rainfall

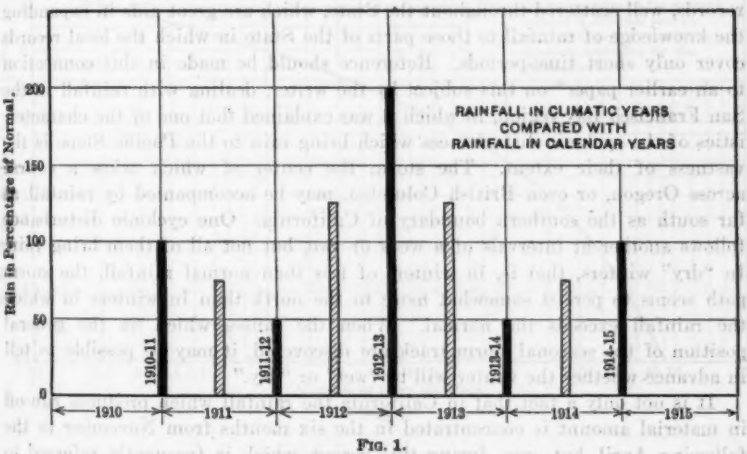

FIG. 1.

is not coincident in time with rain, and as October has been made the first month of the run-off year, it would seem to be desirable to let the "rain" or "precipitation" or "climatic" or "seasonal" year begin with September 1st. It will make no difference on the Pacific Slope whether July and August are placed at the beginning or the end of the climatic year, but as these months are months of heavy rainfall at some points of the East and South, a concession would be readily made, as indicated, to have them placed at the end of the rain-year instead of at its beginning, as is now the practice in California. This, in fact, was the plan, many years ago, of the State Engineer of California, whose compilation of rainfall data was published, in 1886, by the State of California in "Physical Data and Statistics," for climatic or rain-years beginning with September.

If the Weather Bureau declines to make such an innovation, it should at least publish the annual tables applying to Pacific Coast stations in a form

made convenient for use by the addition of a column to its annual tables, in which the totals for the rain-year terminating with June or with August are given.

This paper is intended to point the way to a better understanding of rainfall records and their application to a determination of the water resources and run-off phenomena of any particular region. In order to avoid misunderstandings, however, it will not be amiss to repeat that it has special application to the rainfall conditions of California, which in some essentials are different from those of the East. Thus, for example, it is generally known that wherever in this State the normal annual rainfall (this term being used to include melted snow) is upward of 10 in., an occasional minimum seasonal rainfall of about 30% of the normal (rarely less than 40%) is to be expected and that the maximum may be placed at about 200 per cent. On the Atlantic Coast, no such extreme variation has been observed. The ordinary range there is from about 25% below the annual normal to about 25% above the normal.

California is fortunate in having quite a number of long-time rainfall records, well scattered throughout the State, which are great aids in expanding the knowledge of rainfall to those parts of the State in which the local records cover only short time-periods. Reference should be made in this connection to an earlier paper* on this subject by the writer, dealing with rainfall in the San Francisco Bay region, in which it was explained that one of the characteristics of the cyclonic disturbances which bring rain to the Pacific Slope is the vastness of their extent. The storm the center of which takes a course across Oregon, or even British Columbia, may be accompanied by rainfall as far south as the southern boundary of California. One cyclonic disturbance follows another at intervals of a week or two, but not all of them bring rain. In "dry" winters, that is, in winters of less than normal rainfall, the storm path seems to persist somewhat more to the north than in winters in which the rainfall exceeds the normal. When the causes which fix the general position of the seasonal storm track are discovered, it may be possible to tell in advance whether the winter will be "wet" or "dry."

It is not only a fact that in California the rainfall which produces run-off in material amount is concentrated in the six months from November to the following April, but even during this period, which is frequently referred to as the "wet season", the fair days are more numerous than the rainy ones. Thus, for example, a curve has been constructed to show the frequency of rain for San Francisco. Although this study of rain frequency was made 20 years ago† the result may be accepted as applying to-day. It was found, as shown graphically in Fig. 2, that the average number of days per climatic year (12 months):

With some rain is 66 days;
With more than 0.25 in. of rain is 28 days;
With more than 0.50 in. of rain is 16 days;
With more than 0.75 in. of rain is 10 days; and
With more than 1.00 in. of rain is 6 days.

* "Rain and Run-Off near San Francisco, California," *Transactions*, Am. Soc. C. E., Vol. LXI (1908), p. 496.

† "Report on a Sewerage System for San Francisco," by C. E. Grunsky, Marsden Manson, and C. L. Tilton.

And that there may be expected:

A day with more than 2.00 in. of rain less than once a year;
A day with more than 3.00 in. of rain once in 5 years;
A day with more than 4.00 in. of rain once in 25 years; and
A day with 5 in. of rain very rarely.

Although such facts as these are of hardly more than local interest, nevertheless, they indicate the scope of studies relating to the weather and to rainfall, which may have a bearing on the water output of a water-shed, or on the maximum storm flow, and for this reason they have been referred to here.

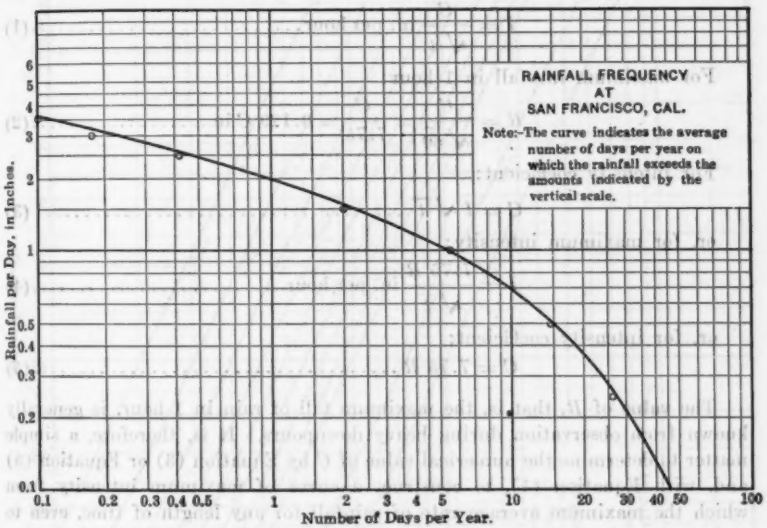

FIG. 2.

INTENSITY OF RAINFALL.

When, in 1892, in connection with the planning of storm-water conduits, information was needed in San Francisco relating to the intensity of rainfall, the Weather Service had nothing to offer except the following: "It never rains in San Francisco an inch an hour, and there is, therefore, no need of a rain intensity record". Needless to say, this idea no longer prevails, and it is now well known that although 1 in. of rain in 1 hour is highly improbable in San Francisco, there are short periods in which that rate of rainfall is greatly exceeded. For any place in the United States, it may be assumed (as amply verified by records of heavy rainfall) that the average rate of rainfall is inversely proportional to the square root of the time to which this rate applies. The following formula, therefore, will be found to give a dependable value of the maximum average rain intensity to be expected in any time-period during which there is heavy rainfall, when observations are

available which disclose the maximum quantity of rain which has fallen in the severest storms in some comparatively short time-period, such as in 30 min., 1 hour, or even in several hours.

Let I = the maximum average rain intensity during t min., in inches per hour.

t = the time, in minutes, to which the rain intensity, I, applies;

R = the maximum quantity of rain to be expected in 1 hour; and

C = a coefficient of definite value for any locality, but not of the same value for different localities.

Then, for maximum intensity:

$$I = \frac{C}{\sqrt{t}} \text{ in. per hour} \quad (1)$$

For maximum rainfall in 1 hour:

$$R = \frac{C}{\sqrt{60}} = \frac{C}{7.75} = 0.129\ C \text{ in.} \quad (2)$$

For intensity coefficient:

$$C = I\sqrt{t} \quad (3)$$

or, for maximum intensity:

$$I = \frac{7.75\ R}{\sqrt{t}} \text{ in. per hour} \quad (4)$$

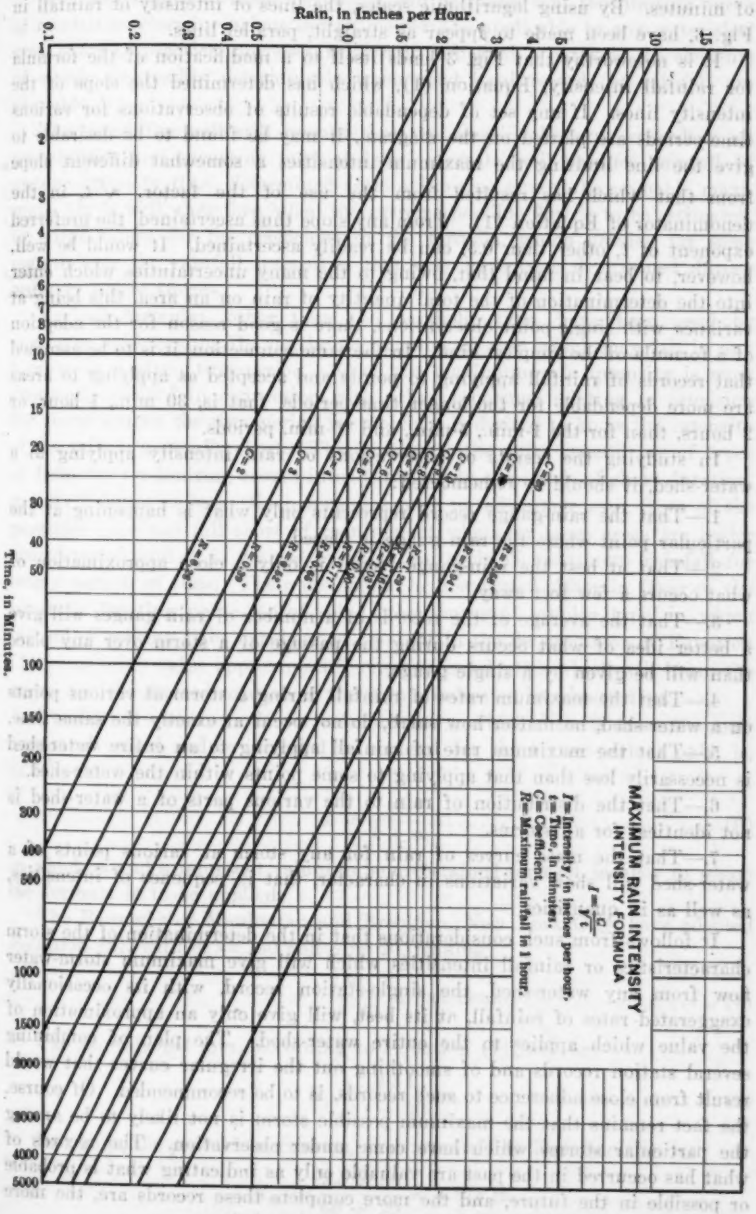
or, for intensity coefficient:

$$C = 7.75\ R \quad (5)$$

The value of R, that is, the maximum fall of rain in 1 hour, is generally known from observation during heavy downpours. It is, therefore, a simple matter to determine the numerical value of C by Equation (3) or Equation (5) and, with Equation (1), to construct a curve of maximum intensity from which the maximum average rate of rainfall for any length of time, even to 24 hours and longer periods, can be scaled off. To have certain single-station records depart materially from the curve need not be disturbing, because such records are subject to unavoidable error, depending on the direction, force, and character of the wind, uniformity of exposure of the rain gauge to all points of the compass, and other like causes.

It may be noted that, for rainfall conditions similar to those in San Francisco, the value of C in Equation (1) is about 5 and for conditions similar to those in New York City, it is about 15. The maximum rainfall in 1 hour throughout any considerable part of San Francisco will rarely exceed 0.60 in. and, in New York City, it will rarely exceed 2 in.

The diagram, Fig. 3, in which the relation between the maximum average intensity of rainfall for various time-periods, from 1 min. to 5 000 min., and for a number of values of the intensity coefficient, C, is shown, will be found to be helpful first, in determining the value of C when the maximum rain in 1 hour, or some other time-period, is known; and, thereafter, in determining by the aid of this value of C, the maximum intensity of rain in any number



Rain, in Inches per Hour.

MAXIMUM RAIN INTENSITY
INTENSITY FORMULA
$I = \frac{C}{\sqrt{t}}$
I = Intensity, in inches per hour.
t = Time, in minutes.
C = Coefficient.
R = Maximum rainfall in 1 hour.

FIG. 3.

of minutes. By using logarithmic scales, the lines of intensity of rainfall in Fig. 3, have been made to appear as straight, parallel lines.

It is noteworthy that Fig. 3 lends itself to a modification of the formula for rainfall intensity, Equation (1), which has determined the slope of the intensity lines. If any set of dependable results of observations for various time-periods are platted on the diagram, it may be found to be desirable to give the line limiting the maximum intensities a somewhat different slope from that which has resulted from the use of the factor, $\sqrt{t}$, in the denominator of Equation (1). From any slope thus ascertained, the preferred exponent of t, other than 0.5, can be readily ascertained. It would be well, however, to bear in mind that, owing to the many uncertainties which enter into the determination of the total quantity of rain on an area, this being at variance with single-point observations, there is good reason for the adoption of a formula of the simplest kind. In the same connection, it is to be assumed that records of rainfall applying to points and accepted as applying to areas are more dependable for the longer time-periods, that is, 30 min., 1 hour, or 2 hours, than for the 1-min., 5-min., and 10-min. periods.

In studying the results of observations of rain intensity applying to a water-shed, it should be remembered:

1.—That the rain-gauge record represents only what is happening at the particular point where the rain guage is placed.

2.—That at best the rain-gauge record is only a close approximation of what occurs a few feet away.

3.—That the average of the records of a number of rain gauges will give a better idea of what occurs during the passage of a storm over any place than will be given by a single gauge.

4.—That the maximum rates of rainfall during a storm at various points on a water-shed, no matter how small, do not occur at exactly the same time.

5.—That the maximum rate of rainfall applying to an entire water-shed is necessarily less than that applying to some points within the water-shed.

6.—That the distribution of rain to the various parts of a water-shed is not identical for all storms.

7.—That the mass curves of rain for any storm at various points of a water-shed will show variations in character, that is, sequence of intensities, as well as in quantities.

It follows from such considerations that in the determination of the storm characteristics or rainfall intensities which will give maximum storm-water flow from any water-shed, the single-station record, with its occasionally exaggerated rates of rainfall, at its best, will give only an approximation of the value which applies to the entire water-shed. The plan of combining several station records and of smoothing out the irregular curves that would result from close adherence to such records, is to be recommended. Of course, the fact remains that the maximum possible storm is not likely to be among the particular storms which have come under observation. The records of what has occurred in the past are valuable only as indicating what is probable or possible in the future, and the more complete these records are, the more dependable will be the conclusions which are based thereon.

With due regard to these matters, it will be found that the limiting curve of rainfall maxima in various short time-periods, applicable to any water-shed area, is for all practical purposes, as already indicated, a parabola the elements of which are readily determinable when good local records of rainfall are available.

The possibility will still remain that the occasional storm, exceeding all probabilities and occurring only at long intervals, will produce rainfall of greater intensity than, determined from a limiting curve, the probable maximum. It is well, therefore, when the extreme possible flow is to be estimated, to adopt values for the coefficient in the formula, which provide for some margin over the rainfall intensities that may have been determined during ordinary severe storms.

Various formulas, other than the parabolic type, have been used by engineers to determine the maximum quantity of rain which may fall in any locality in a given time-period. Since the maximum rain intensity is most frequently desired in connection with urban problems, relating to provision for storm waters, the time-period for which it is desired to know the intensity of the rain is generally short. This has led to the quite general use of types of formulas for limiting curves intended to apply to periods of short duration, usually 2 hours or less. Such formulas have no advantage over those of the parabolic type and fall short of requirement whenever large areas are under consideration and it is desired to know the probable maximum rainfall for longer periods of time. Their use should be abandoned either in favor of the parabolic limiting curve, or of some other curve of similar type, in which instead of making t the exponent of one-half in the denominator of Equation (1), some other value approximating one-half is adopted, which will bring the curve into the desired relation to the points indicated by observation.

The best known formula for rain intensity, which departs from the type herein advocated and is intended to be used for short time-periods only, is, as follows:

$$I = \frac{m}{t + n} \qquad (6)$$

in which m and n represent values to be ascertained for each locality to which the formula is to be applied.

The Boroughs of Manhattan and Brooklyn, New York City, have adopted Equation (6), with $m = 150$ and $n = 20$, making

$$I = \frac{150}{t + 20} \text{ in. per hour} \qquad (7)$$

The rainfall in t min., according to Equation (7), will be:

$$R_t = \frac{2.5\,t}{t + 20} \text{ in} \qquad (8)$$

In 1 hour, the probable maximum, as determined by Equation (8), is:

$$R_{60} = \frac{2.5 \times 60}{60 + 20} = 1.875 \text{ in.}$$

For this value on a parabolic limiting curve, it will be found that:

$$I = \frac{14.5}{\sqrt{t}} \quad \ldots\ldots\ldots\

parisons to substitute for inches of seasonal rain (that is, precipitation in a rain-year or 12 months), the relation in percentage which the rainfall of the particular 12 months in question bears to the normal rainfall. This is practicable whenever a few long-time rainfall records disclosing a dependable normal afford a good starting point. These records at what may be called primary base stations should cover a time-period of such length that a few additional seasons of either light or heavy rainfall would not materially change the value of the annual normals for these stations.

TABLE 2.—RAINFALL AT SAN FRANCISCO AND SACRAMENTO, CAL., FOR THE PERIOD 1849 TO 1919, EXPRESSED IN PERCENTAGE OF THE NORMAL SEASONAL RAINFALL

Normal annual rainfall at San Francisco = 22.7 in.
Normal annual rainfall at Sacramento = 19.0 in.

Referring now to California, the records at San Francisco and at Sacramento, beginning in 1849, may be accepted as of this type. These records are presented in Table 2, the rainfall being expressed in percentage of normal. In Column (4) there is given a composite record, a combination of the two separate records, which is a fair index of the rainfall throughout a broad extent of central areas in California.

With the information contained in Table 2, all other rainfall records in the vicinity, beginning with those nearest, and those covering the greatest number of seasons, can be expanded to the full 70-year period of the base stations; and, thereupon, progressing into zones farther removed from the two primary base stations, by the use of secondary base stations, the remaining—often quite fragmentary—rainfall records of the State can likewise be expanded from short-time records of observed rainfall to long-time records of estimated rainfall. Thus, the normal annual rainfall can be determined for all places at which records have been kept. The percentage of normal rainfall noted for any place and season is, at once, an indication of the quantity of rain which fell in the vicinity of that place.

To illustrate the procedure, take Napa where the mean annual fall of rain during thirty-seven seasons, between 1877 and 1919, covered by records, was 24.3 in. The composite record in Table 2 shows that for these same years the mean annual rainfall was 103% of the normal rainfall. Consequently, the normal at Napa is $\frac{24.3}{1.03}$, or 23.6 in., and the Napa rainfall for each year of the 70-year period not covered by actual observation will be found by applying the percentage of normal in the composite column (Column 4) of Table 2 to the normal for this station. The results thus obtained will be practically as dependable as a basis for water production or run-off studies as if there had been actual measurement of rainfall at Napa during the full 70-year period. This is true, because a deduced record of this character, although departing more or less from what did actually take place, nevertheless, fairly represents the probable annual fluctuations in the rainfall and also quite dependably the range from probable minimum to probable maximum. It is possible in this fashion, as stated, to expand the rainfall records for any part of California and thus to produce for any region of the State a dependable long-time rainfall table generally covering the full period from 1849 to 1921.

Frequency of Wet and Dry Seasons.

It is interesting to study probabilities of seasonal rain intensity on the basis of the rainfall records of the past. Taking, for example, the composite record of the two California primary base stations, Table 2, and platting the same as ordinates in the order of their magnitude, a graph such as is shown in Fig. 4, will result.

or, expanded to 100 years, to express probabilities in percentage, the curve will show that, in the region to which it applies, the rainfall in climatic years will range from a minimum of about 30% to a maximum of about 210% of the normal. In any considerable number of years, when grouped according to the rainfall, there will be:

Less than	30%	of	normal	rain	in	0.5%	of all the	years
30 to	40%	of	normal	rain	in	1.1%	of all the	years
40 to	50%	"	"	"	"	3.3%	thereof

More than	200%	"	"	"	"	1.4%	"	

In a broad way it appears from the foregoing and from the diagram, Fig. 4, that in the central parts of California the precipitation in about 26.5% of the climatic years will be within 10% of the normal; that the precipitation in about 55% thereof, will be below normal; and that the precipitation in about 45% will be in excess of normal. It also appears that a climatic year

with less rainfall than 30% of the normal is highly improbable and that there will be occasional seasons with 100% more rain than normal. In diagrammatic form, this information is presented in Fig. 5.

Normal Seasonal Rainfall to Any Date.

As each season or climatic year advances, a comparison with the rainfall to date of a normal season is frequently desirable, and this information, for a limited number of places in California, is being furnished to the public from day to day, through the press, by the local U. S. Weather Bureau forecasters. It has been the practice to compute, on the basis of past records for each station, the normal fall of rain to each date. Instead of this practice, the following graphic method of procedure for regional application is suggested.* For any station or for a composite as already described the mass curve of seasonal rain is platted, using monthly normals and calling the seasonal normal 100%, as shown in Fig. 6. The resulting curve will give for any day

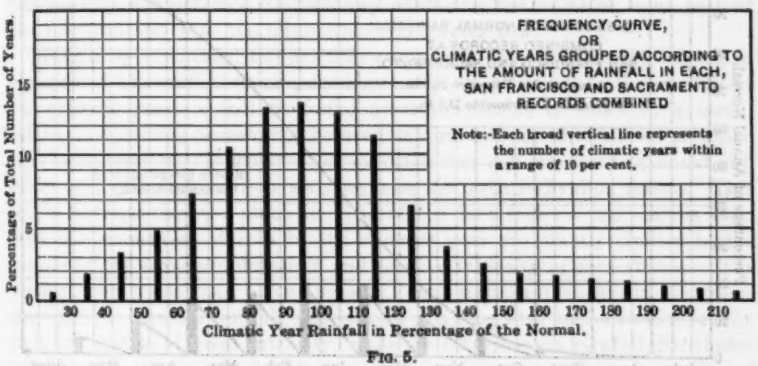

Fig. 5.

of the year the normal seasonal rain to that day in percentage of the annual normal. If, now, the estimated seasonal normal for any station within the region to which a curve of this kind applies, decreases or increases, due to one or more dry or very wet seasons, this change will not materially affect, if at all, the shape of the curve for normal climatic years, but the estimated normal rain to any date will automatically change in the same ratio as the annual normal. A further advantage of using such a mass curve lies in the fact that minor irregularities which appear when the actual mean precipitation to each day of the year is used, are smoothed out, and the true relation of the part-year normal (being the normal to a given date) to the seasonal or full-year normal is more dependably approximated.

The curve, as shown in Fig. 6, being based on the first-class records of rainfall at San Francisco and at Sacramento, is substantially correct for any place in Central California. To illustrate the use of this seasonal mass curve, it may be noted that for February 14th, the normal rainfall applying to that date (being for the season which began on the preceding first day of July) is

* *Journal of Electricity*, Vol. 44, No. 5 (March 1st, 1920).

given by the U. S. Weather Bureau at 14.4 in. for San Francisco and at 12.2 in. for Sacramento. For this date the curve, Fig. 5, shows that 64% of the normal rainfall for a year should have already fallen. For San Francisco, with a normal annual rainfall of 22.7 in., this is 14.5 in. and for Sacramento with a normal annual rainfall of 19.0 in., it is 12.2 in.—values which agree with those determined by the Weather Bureau.

Effect of Altitude on Precipitation.

The attempt is frequently made to establish a relation between the annual rainfall and altitude. A glance at any map showing isohyetose lines will indicate the futility of searching for any such relation that would be widely applicable. It will be found that usually where cyclonic disturbances, accompanied by rain, bring up against, or cross, mountain ranges, the rainfall will be heavier well up on the mountain slope than at the base of the range and that on the

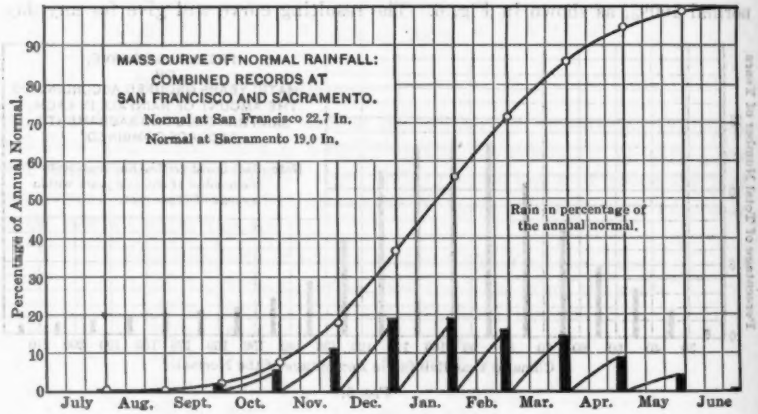

Fig. 6.

far side of the range there will be light rainfall, even though the mountains there may be flanked by a high plateau. The gradient represented by the distance between the isohyetose lines compared with their rain interval, however, may bear almost any kind of a relation to the gradient of the ground surface, and near the summit of the range there is frequently, perhaps it might be said usually, a reversal of the gradient; that is, the region of greatest rainfall is not ordinarily on, but rather somewhat below, the summit of the ridge. It is to be noted, however, that, speaking broadly, the isohyetose lines, or lines of equal quantities of rain, run parallel with the general course of the contour lines of the country. It is, therefore, comparatively easy to extend the isohyetose lines over considerable areas, in regions in which the fall of rain and snow at a few controlling points has been ascertained.

The range in the annual quantities of rain and snow from the western base of the Sierra Nevada, California, across these mountains into Nevada in the latitude of Oroville, increases from about 20 in. in the Sacramento Valley to a greatest precipitation of about 80 in. per annum at elevations about 1 000 ft.

below the crest of the range. On the high plateau to the eastward of the main range, the precipitation drops to less than 10 in. per annum, or only about one-eighth as much as at the same elevation on the western slope of the range.

Run-Off in its Relation to Rainfall.

Closely associated with a study of the rainfall in any region is the study of the run-off which results from the rain. The engineer is interested both in the rate at which this run-off occurs and in the quantity thereof in a considerable time-period, as in a year or in a fraction of a year.

In the study of flood-control projects and in the making of provision for adequate storm-water conduits in urban areas, the engineer is particularly concerned with the maximum rate of run-off which the rainfall on a water-shed can produce. In the study of water-power utilization and the making of stream flow available for irrigation and for domestic and industrial use, the engineer is more particularly interested in the dependable quantity of water produced by a water-shed continuously or during the whole or some part of the year and also with the minimum or low-water flow.

Taking up first, then, the probable annual run-off, or rather the run-off in a period of 12 months, which may reasonably be attributed to the rainfall of the climatic year, it will be found quite practicable to establish a useful relation, expressing probability, between this run-off and the rainfall to which it is to be ascribed. It must not be expected that any law can be pointed out, which will give this relation with accuracy for each individual season. This would be expecting too much in view of the fact that no two seasons even with like quantities of rain in the climatic year are exactly similar in the matter of the sequence, duration, and relative intensity of rain storms. It is readily conceivable that, of two seasons (climatic years), each with the same aggregate or seasonal rainfall, one may be of a type with concentration of rain in a few storms of great intensity, while the other has its rainfall distributed to numerous storms with barely enough rain to saturate the surface soil and with sufficient intervals between storms to permit the soil to lose its water by evaporation. In one case, a relatively large proportion of the rain will find its way to the stream; in the other, very little run-off may occur.

The matter is complicated still further in regions where the rainfall, instead of being concentrated in a certain part of the year, is distributed fairly uniformly to the 12 months. In this event, transpiration as well as evaporation may vary within wide limits, particularly in the warm summer months, being affected by the sequence of rains and the great range in the resulting conditions of sunshine, soil moisture, temperature, wind, and other factors which determine the rate at which water, that would otherwise appear in the stream, is carried off by the atmosphere.

Despite any admission that no dependable estimate of run-off can be made for any single year from the known rainfall conditions which cause this run-off, it is, nevertheless, of the utmost importance to determine the ordinary or probable relation between the rain and its effect on the flow of the stream. It is self-evident that no one can predict the rainfall as to time and quantity for future seasons except on the basis of past records. The same amount and

frequency of departures from the normal or probable conditions are to be expected in the future as have been noted in the past. It is only with full appreciation of this limitation on estimated water yield and estimated maximum and minimum flow, that the relation of run-off to rain should be studied. Otherwise, there will be some disappointment and hesitancy in using results, particularly when station records of rainfall are expanded to long time-periods by the plan advocated by the writer. Nevertheless, for such conditions as prevail in the Pacific Coast States, the method is justified and in most cases the results may be accepted as being quite as dependable as though a complete rainfall record was available for each station for which a fragmentary record has been expanded to a full-period record.

The first rain that falls wets the surface of the ground. A continuation of a gentle rain may be at a rate but little if any in excess of that at which the penetration of moisture into the soil takes place. Thus, considerable rain may fall before there is any material run-off. In the interval thereafter, between one rain storm and the next, the wet ground dries out more or less, its water loss being into the atmosphere by evaporation. If the surface of the ground is kept wet by successive rain storms so that the evaporation, which is greater from a saturated soil than from one that is partly dried out, will be kept at a relatively high rate throughout the time between rain storms, there may be a great loss of water by evaporation. If the rainfall for the climatic year is very light, the time during which the soil is wet and evaporation rapid will be short; consequently, in such years, evaporation will take less of the rain water than it will in wet years. On the other hand, however, if the number of rainy days is great, and the conditions favoring evaporation, by reason of the long time during which the atmosphere is saturated, are poor, then, even with a saturated condition of surface soils, there may be less evaporation than if a fairly regular alternation of a rainy period of a few days with a dry period of similar duration occurred.

It appears from these considerations that evaporation will take more of the water falling as rain in fairly wet years than in dry years and that evaporation (including transpiration) may take from the soil practically all the water which falls in dry years, when the rainfall is very light, leaving nothing to go to the stream. The probable ratio of evaporation to rainfall will decrease as the seasonal quantity of rain increases to some more or less indefinite limit and, conversely, the proportion of rain water which reaches the stream as run-off will increase. This fact was recognized by the writer many years ago and led him to formulate for California the following rule, announced in the earlier paper already referred to, which is applicable in ordinary cases with a fair degree of approximation:

The percentage of the probable run-off due to a rainfall of less than 50 in. in a climatic year of 12 months will be as high as there are inches of rain. The probable run-off due to a rainfall in excess of 50 in. in a climatic year will be 25 in. less than the rainfall; or, expressed by the formula (P = precipitation):

$$r = 0.01\ P^2, \text{ for } P \text{ less than } 50 \text{ in.} \quad (11)$$

$$r = P - 25, \text{ for } P \text{ greater than } 50 \text{ in.} \quad (12)$$

In Equations (11) and (12), P represents the rainfall or precipitation, in inches, in a climatic year, on any water-shed, and r the run-off depth, in inches, over the same area, resulting from this rainfall.

Later studies seem to indicate that quite generally throughout the United States where the precipitation is from 40 to 80 in., the soil and plants growing on the soil will take and dispose of from 22 to 28 in. of water and the remainder will appear in the stream as run-off.

Referring now more particularly to such conditions as prevail in California, the result of the writer's run-off studies early led to the use of two curves, one of which was intended to express the probable relation of run-off to rain in the low or foot-hill regions of the State and the other, showing a somewhat larger proportion of run-off, was intended to show the probable

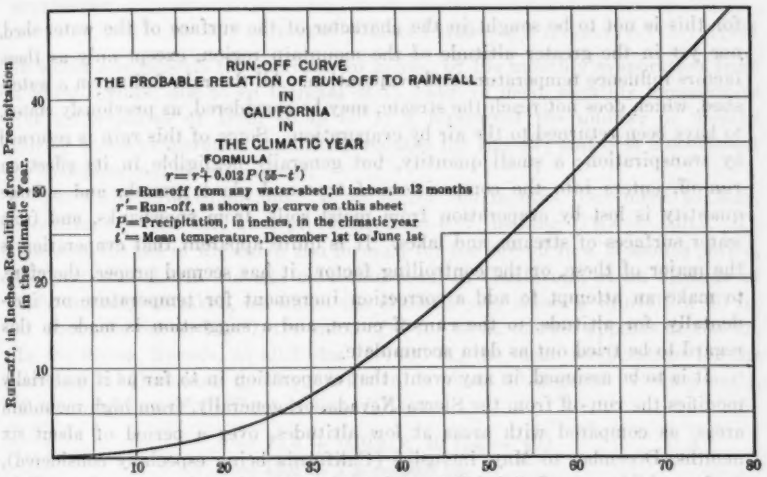

FIG. 7.

relation of run-off to rain in the higher mountain regions of the Sierra Nevada.* It will not be necessary to reproduce these curves which now have only historic value. In revised form, however, a curve is shown in Fig. 7, which takes the place of the original curve for low areas and which shows quite dependably the probable relation between the rainfall of the climatic year and the resultant run-off for California conditions.†

Expressed in tabular form, the writer's run-off curve for water-sheds in California at low altitude gives the values shown in Table 3, which values apply to the run-off resulting from the rainfall in a climatic year of 12 months.

EFFECT OF TEMPERATURE ON RUN-OFF.

It has been found, however, as already suggested that, if applied to high mountain areas, this curve (Fig. 7) would show too little run-off. The cause

TABLE 3.—THE RELATION OF RUN-OFF TO RAINFALL, CALIFORNIA CONDITIONS.
(Rain includes snowfall)

Rain, in 12 months of climatic year, in inches.	Resulting run-off, in inches.	Rain, in 12 months of climatic year, in inches.	Resulting run-off, in inches.	Rain, in 12 months of climatic year, in inches.	Resulting run-off, in inches.
5	0.3	24	4.1	55	27.0
10	0.6	26	5.0	60	32.0
12	0.8	28	6.0	65	37.0
14	1.1	30	7.0	70	42.0
16	1.5	35	10.0	75	47.0
18	2.0	40	13.6	80	52.0
20	2.6	45	17.7	90	62.0
22	3.3	50	22.4	100	72.0

for this is not to be sought in the character of the surface of the water-shed, nor yet in the greater altitude of the mountain region, except only as these factors influence temperature and evaporation. All the rain falling on a water-shed, which does not reach the stream, may be considered, as previously stated, to have been returned to the air by evaporation. Some of this rain is returned by transpiration; a small quantity, but generally negligible in its effect on run-off, enters into the composition of tree and plant growth, and a large quantity is lost by evaporation from moist soils, from snowbanks, and from water surfaces of streams and lakes. It is quite apparent that evaporation is the major of these, or the controlling factor; it has seemed proper, therefore, to make an attempt to add a correction increment for temperature or, incidentally, for altitude, to the run-off curve, and a suggestion is made in this regard to be tried out as data accumulate.

It is to be assumed, in any event, that evaporation in so far as it materially modifies the run-off from the Sierra Nevada, or, generally, from high mountain areas, as compared with areas at low altitudes, over a period of about six months, December to May, inclusive (California being especially considered), during which snow is on the ground or the ground surface is moist, will be fairly determinable from the temperature of the air.* It may be noted, too, that any such correction for temperature will represent a larger proportion of the run-off when the precipitation is light than when it is heavy. It is true, however, as already noted, that the aggregate evaporation from areas subject to California winter conditions of wetting by snow or rain must be regarded as increasing with increasing precipitation. These considerations have led to the establishment of the correction factor for altitude, or, better, for the lower temperature due to altitude, as appears in the following formula:

Let P = again the rainfall or precipitation, in inches, during the 12 months of the climatic year;

r' = the depth of run-off, in inches, resulting from the precipitation, P, as shown by the curve, Fig. 7, for areas at low altitude;

r = the depth of run-off, in inches, resulting from the precipitation, P, on any area at any altitude; and

* See the writer's discussion of "Evaporation", *Transactions*, Vol. LXXX (1916), p. 1963.

f = the mean temperature, in degrees Fahrenheit, that prevails throughout the water-shed during the period in which evaporation materially affects the run-off. For California, this period will be from December to May.

The formula may now be written for California, as follows:

$$r = r' + 0.012\ P\ (55 - f) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

At a temperature of 55° for the months, December to May, there will be no correction to the values shown by the run-off curve, Fig. 7, at sea level; but as the elevation increases and the temperature falls, there will be an increment of water, due to less evaporation, to be added to the run-off.

The foregoing formula, Equation (13), was deduced from the more general expression:

$$r = r' + C\,n\,e\,P\ (55 - f) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

in which e represents the increase, in inches, of the monthly evaporation from a water surface, due to an increase of 1° Fahr. in mean monthly temperature (at temperatures of from 40 to 60°); n represents the number of months during which evaporation materially reduces the run-off; and C is a coefficient to be determined by experiment.

For California conditions,* $n = 6$, for the months, December to May, inclusive, $e = 0.1$ in.; and, probably, $C = 0.02$, making $C\,n\,e = 0.012$. To illustrate the use of the curve and formula for the run-off in a 12-month period, the case of a Sierra Nevada mountain area, in California, at an altitude of 6 000 ft., may be taken, on which the climatic year shows a rainfall of 40 in.

From the curve, Fig. 7, the value of r' for 40 in. of rain appears at 13.6 in. In the Sierra Nevada, at altitudes of 6 000 ft., the mean temperature for the six months, December to May, inclusive, is about 40 degrees. Consequently, the seasonal run-off by formula is as follows:

$$r = 13.6 + 0.012 \times 40\ (55 - 40)$$
$$r = 13.6 + 7.2 = 20.8 \text{ in.}$$

It will be noted from this illustration that, due to low temperature at high altitudes, there may be a material increase in the proportion of rain which finds its way to the stream.

Normal Run-Off Computed from Rainfall Records.

After the relation between seasonal (12 months) rainfall and probable run-off has been established by some such curve as that shown in Fig. 7, in figures such as those presented in Table 3, or by the formula, Equation (13), it becomes possible to compute the probable or normal run-off for each 12-month period, for any region, from the rainfall record, when the rainfall is expressed for each season in percentage of the normal rainfall. For all practical purposes and particularly as a means of forecasting future run-off, this method may be accepted with confidence. It leads to a computed record of stream flow which will show what the water output of the stream has been and what water output is to be expected in the future. It shows, too, the relation of the

* *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1968.

water output in minimum and maximum years to the normal water production and also the frequency of years of ordinary, small, and large water production.

As an illustration, a stream may be selected on the water-shed of which the mean annual rainfall has been found to be 30 in. and the seasonal variation of which in the quantity of rain is represented by the composite rain record noted in Table 2.

It follows that in this water-shed, in a series of 100 years, rainfall and run-off will occur about as set forth in Table 4.

TABLE 4.—Computation of Normal Annual Run-Off for a Normal Seasonal Rainfall of 30 in. from a Water-shed at Low Altitude in a Region for Which the Composite Record of Rainfall at San Francisco and Sacramento is Typical.

Number of climatic years.	Rainfall in percentage of normal.	Annual rainfall, in inches.	Resulting annual run-off, in inches.	Total run-off for period, in inches.

1.4	205	61.5	33.50	46.90
100.	.....	.....	.....	804.58
Mean.....	100	30.0	.....	8.0

According to the calculation presented in Table 4, the normal run-off for a normal seasonal rainfall of 30 in. (that is, within a climatic year of 12 months), is 8.0 in. from a water-shed at low altitude in central parts of California. The probable run-off, on the other hand, resulting from a like quantity of rain, that is, 30 in., during any single climatic year, according to the curve, Fig. 7, or Table 3, is 7.0 in. The normal annual run-off, therefore, from a water-shed at low altitude, throughout which the normal annual rainfall is 30 in., exceeds the probable run-off, due to a like quantity of rain in the single climatic year, by 1 in., or by about 14 per cent. A similar calculation of the normal run-off when the normal rainfall is 20 in. will show an excess over the probable single season run-off, for a like quantity of rain, of about 19 per cent. For a normal seasonal rainfall of 40 in., the excess is 9%; for a normal seasonal rainfall of 50 in., it is 3%; and for a normal seasonal rainfall of 60 in., the normal annual run-off will be about 2% less

than that which is probable in any single climatic year with a rainfall of 60 in.

These relations apply, as noted, to a region in which rainfall conditions are correctly represented by the composite rainfall records, as shown in Fig. 3, applying to certain central areas of California. Where the variation in the rainfall in the several climatic years of a long time-period departs from that shown by this diagram, a different relation between the normal seasonal run-off and the estimated or probable run-off in a season with a rainfall equal to the normal may be found. The numerical illustration is intended merely as a guide in making run-off studies. A different relation will be found, too, when correction factors are applied for altitude or temperature departures from those to which the run-off curve, Fig. 7, applies.

When the run-off is to be determined from a water-shed of so great an extent that there is a wide range in the normal rainfall on different portions thereof, it should be subdivided, preferably in such fashion that the range of normal rainfall in each subdivision will not exceed 5 in., and the estimate of the year's run-off from each subdivision can then be made separately.

The isohyetose lines shown in Fig. 8, for a low to high mountain region lying to the eastward of Oroville, Cal., may serve to illustrate not only the considerable variation of normal annual rainfall within comparatively short distances, but also the difficulty that would exist, in such an area as that covered by the diagram, of estimating the average normal annual rainfall for the entire area from a few isolated station records without recourse to isohyetose lines.

Elements of Uncertainty.

In concluding this discussion of the relation of run-off to rainfall, it may be noted that the problem is complicated by the difficulty always encountered of determining the precipitation on any area of considerable extent, as well as by the lack of precision in the estimates of stream flow. The crudest kind of approximation must usually be resorted to in the matter of rainfall. When water-sheds, for which the shape of the isohyetose lines is known, are studied in relation to rainfall records at a few individual points, the opportunity for error in this particular becomes clearly apparent. In the case of drainage areas such as those in the high mountains of California, for example, there is much uncertainty, too, as to the normal annual snowfall and the snowfall in any individual season. Even for any single point this statement holds good. The distribution of snow over considerable areas with all kinds of exposure to the wind cannot be uniform, and there is uncertainty, too, as to the quantity of water which any given depth of snowfall may represent. The few records of precipitation in California's snowbelt, which are available, are, at best, to be accepted as approximate only, and, yet, it appears that, generally, in respect to precipitation distribution, the information available in this State is as reliable as any elsewhere in the United States.

Maximum Storm-Water Flow from Small Areas.

A complete discussion by the writer of the storm-water flow problem as applied to urban areas will be found in his paper on "The Sewer System

of San Francisco."* The value of the deduced formulas, as there presented, may be reaffirmed, and a wider application may be claimed for them, provided only that fair information is obtainable from past records of rain intensities throughout the affected areas. The element of greatest uncertainty in any formula for the maximum run-off rate will always be the perviousness of the surface of the water-shed. In each case, allowance for the effect of this perviousness must be made by the engineer, on the basis of experience.

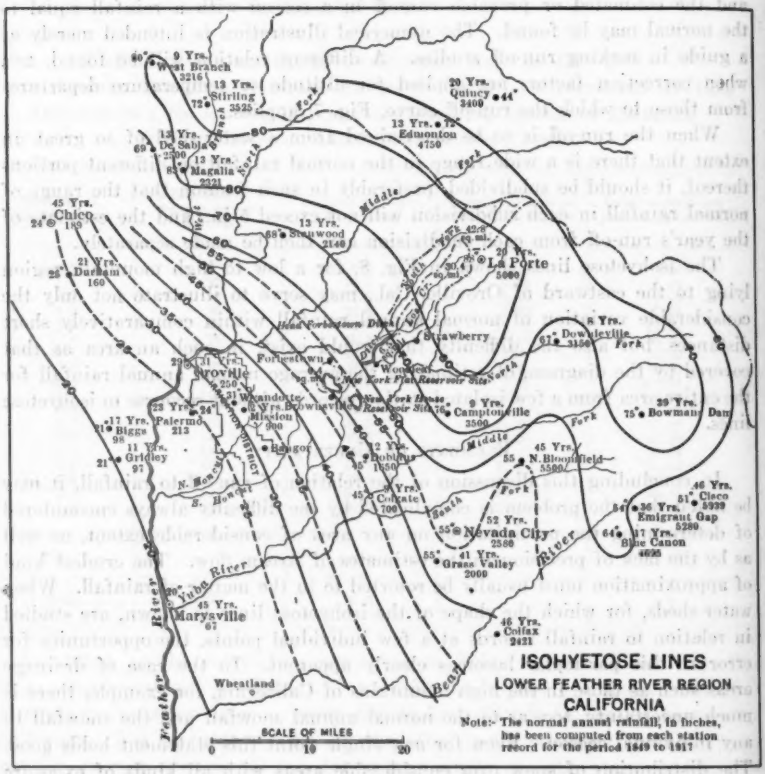

FIG. 8.

Let A_1, A_2, A_3, etc., = the areas of subdivisions of any water-shed, in acres;

A = the area, in acres, of the water-shed;

a, a_1, a_2, a_3, etc., = the coefficients of perviousness, or run-off coefficients, applying to the water-shed and the respective subdivisions thereof;

S = the average slope of the main watercourse, in feet per thousand;

* *Transactions*, Am. Soc. C. E., Vol. LXV (1909), p. 310.

T = the time, in minutes, that it will take water to flow, under maximum run-off conditions, in natural or in proposed conduits, from the most remote part of the water-shed to the point at which the maximum storm-water discharge is to be determined;

t = the critical time, in minutes, during the continuance of a rain-storm for the area under consideration, being that time within which the rain will produce the maximum rate of run-off.

i = the number of minutes which it takes water to flow on the surface of the area under consideration to the points of entry into the conduits;

d_m = the maximum storm-water flow at the point at which flow is to be determined, in cubic feet per second per acre;

D_m = the maximum storm-water flow, in cubic feet per second.

By the aid of the rain-intensity formulas already noted and of observations throughout the water-shed, which establish the maximum quantity of rain which may be expected to fall thereon in periods of 30 min., 1 hour, 2 hours, or some other period, or periods, of time, the value of the intensity coefficient, C, in the formula for I, Equation (1), namely,

$$I = \frac{C}{\sqrt{t}}$$

is to be determined, and the procedure when the capacity to be given to storm-water conduits is in question, will then be as follows:

Divide the water-shed having an area of A acres into three subdivisions, A_1, A_2, A_3, such that the time required by water to flow from the farther limits of the first over the surface and in conduits of the type which are to be provided, will be one-third, and that the time required for water to flow from the most remote parts of the second subdivision, will be two-thirds of the time required for storm-water to flow from the most remote part of the water-shed to the point at which maximum storm-water flow is to be estimated.

Approximate the time, i, in minutes, that it will take water to flow on the surface of the water-shed to the inlets of the conduit system. Estimate the time, T, in minutes, that it will take water to flow from the most remote part of the water-shed to the point at which maximum flow is to be estimated. Then, determine the critical time, t, from the following:

$$t = 0.40 \frac{T}{a A}(a_1 A_1 + 2 a_2 A_2 + 3 a_3 A_3) + i \quad \ldots\ldots\ldots\ldots (15)$$

The coefficient of imperviousness, a, for the entire water-shed is found from the following:

$$a = \frac{a_1 A_1 + a_2 A_2 + a_3 A_3}{A} \quad \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

Consideration must be given to the perviousness of the surface of the watershed in determining the values of a_1, a_2, and a_3. For an entirely impervious surface and relatively small areas, these factors would be unity; for a coarse, well under-drained gravel, they may approximate zero. The values of a, a_1, a_2, and a_3, therefore, will lie somewhere between unity and zero.

For use in a similar formula for maximum flow, the late Emil Kuichling, M. Am. Soc. C. E., based on large experience, recommended* the following:

	Value of a.
For roof surfaces	0.70 to 0.95
" asphalt pavements in good order	0.85 to 0.90
" stone, brick, and wooden block pavements with tightly cemented joints	0.75 to 0.85
" same, with open or uncemented joints	0.50 to 0.70
" inferior block pavements with uncemented joints	0.40 to 0.50
" macadamized roadways	0.25 to 0.50
" gravel roadways and walks	0.15 to 0.30
" unpaved surfaces, railroad yards, and vacant lots	0.10 to 0.30
" parks, gardens, lawns, and meadows, depending on surface slope and character of subsoil	0.05 to 0.25
" wooded areas or forest land, depending on surface slope and character of subsoil	0.01 to 0.20

It is believed, in applying the formulas which are here presented, that it would be better not to attempt the minute classification of surface according to its character, which was suggested by Mr. Kuichling. When small urban areas are under consideration, all surfaces which approximate imperviousness may well be put into one class, because the infiltration of water into the surface material may be neglected when the critical time is short and the rain intensity high.

When larger areas are under consideration, and the soil of the country is an ordinary loam, the approximate values given in Table 5, based on population density, may be used.

TABLE 5.

Population per acre.	Value of a.	Population per acre.	Value of a.
10	0.20	60	0.60
20	0.30	70	0.65
30	0.40	80	0.70
40	0.50	90	0.73
50	0.55	100	0.75

The maximum storm-water flow can now be estimated from the value of I, or from the maximum rainfall, R, in 1 hour, by the formula:

$$d_m = 0.645\, a\, I \text{ sec-ft per acre} \quad (17)$$

making,

$$D_m = 0.645\, a\, A\, I \text{ sec-ft} \quad (18)$$

* *Transactions*, Am. Soc. C. E., Vol. LXV (1909), p. 399.

or its equivalent,

$$d_m = \frac{5\,a\,R}{\sqrt{t}} \text{ sec-ft. per acre} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (19)$$

making,

$$D_m = \frac{5\,a\,A\,R}{\sqrt{t}} \text{ sec-ft.} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (20)$$

In developing this formula, consideration has been given to the effect of the temporary water storage (that is, to the increase or decrease of the volume of water in transit) in the conduits as well as that resting on the surface of the water-shed, on the momentary rate of flow. This is fully explained in the writer's paper* to which reference has already been made.

The value of I is best obtainable from the diagram, Fig. 3, or by Equations (1) to (5). The value of C in the rain-intensity formula, Equation (1), as explained, is dependent on local rainfall conditions. Local records of rainfall, or if no local records are available, then those of some locality with similar meteorological conditions, are to be used in determining the value of C and the resultant rain intensities.

When water-sheds are under consideration, which, though still belonging in the class of small areas, are of so large an extent and so diversified in surface characteristics that the maximum rain intensities in different portions thereof have a wide range, that is, depart widely from the values that would be most applicable for the water-shed treated as a unit, there should be introduced into the calculation the maximum rainfall per hour applying to each subdivision thereof, R_1, R_2, R_3, or the corresponding coefficients, C_1, C_2, C_3, but these should always be determined for the critical time, t, which applies to the entire water-shed.

The formulas may then be written:

$$D_m = \frac{5}{\sqrt{t}} (a_1 A_1 R_1 + a_2 A_2 R_2 + a_3 A_3 R_3) \ldots\ldots\ldots\ldots (21)$$

or,

$$D_m = 0.645\,(a_1 A_1 I_1 + a_2 A_2 I_2 + a_3 A_3 I_3) \ldots\ldots\ldots\ldots (22)$$

The formulas previously noted for maximum run-off are simple in form and convenient for general use. The numerical factors appearing therein have been deduced in part, as previously stated, from a study of the effect of the constantly changing volume of water actually in transit over the surface and in the conduits, that is, of the effect (on the flow) at the gauging point of an increase or decrease of the quantity of water temporarily in storage within the water-shed. The factors which will always be involved in some uncertainty, are the coefficients of perviousness and of rain intensity.

The following example (based on assumed data) will illustrate the application of the formula for maximum stream flow.

* *Transactions*, Am. Soc. C. E., Vol. LXV (1909), p. 294.

A topographical survey and preliminary estimates of the velocity at which water will flow in proposed conduits, have established the following values:

$$\begin{aligned} A &= 2\,500 \text{ acres} \\ A_1 &= 500 \text{ acres}; \; a_1 = 0.90 \\ A_2 &= 1\,200 \text{ acres}; \; a_2 = 0.75 \\ A_3 &= 800 \text{ acres}; \; a_3 = 0.40 \\ T &= 85 \text{ min.} \\ i &= 10 \text{ min.} \end{aligned}$$

The available rainfall records show, for this water-shed, that during one storm 1 in. of rain fell in 2 hours and, at another time, it rained 2 in. in 6 hours. It is known, too, that the storms in which rainfalls of this intensity occurred, were classed as severe, and that both records may be accepted as approaching single-station maxima. Being for application to a fairly large urban area, the values of R and C deduced from these records will probably be somewhat in excess of the probable value for the whole area, and this excess may be considered as some margin of safety, although not quite enough.

The rain intensity of 0.50 in. per hour deduced from the 2-hour record indicates a value of $C = 5.5$; and the rain intensity of 0.33 in. per hour from the 6-hour record indicates a value of $C = 6.2$.

As the extreme rain intensity may exceed that of either of the only two storms for which dependable records exist, it will be proper to introduce C into the calculation at a value of about 6.5.

Then, by Equation (12):

$$a = \frac{0.90 \times 500 + 0.75 \times 1\,200 + 0.40 \times 800}{2\,500} = 0.66$$

by Equation (11):

$$t = 0.40 \left(\frac{85}{0.66 \times 2\,500}\right) (0.90 \times 500 + 2 \times 0.75 \times 1\,200 + 3 \times 0.40 \times 800) + 10 = 76 \text{ min.}$$

by Equation (1)

$$I = \frac{6.5}{\sqrt{76}} = 0.74$$

and by Equation (15):

$$d_m = 0.645 \times 0.66 \times 0.74 = 0.32 \text{ cu. ft. per sec. per acre}$$

and by Equation (16):

$$D_m = 0.32 \times 2\,500 = 800 \text{ cu. ft. per sec.}$$

This is the estimated maximum storm-water flow from the 2 500 acres.

Maximum Stream Flow or Maximum Rate of Run-Off from Large Areas.

When the capacity is to be prescribed of a spillway for a storage reservoir, or of a stretch of river to which flood-waters are to be confined, larger areas come under consideration than in the case of ordinary urban problems. It is

then desirable to express areas in square miles instead of in acres. With this change of area unit, but again under the assumption that meteorological conditions and, therefore, values of R, the maximum rainfall in 1 hour, and of I, the maximum average rate of rainfall in the critical time-period, t, may be considered to be uniform throughout the water-shed, there will be:

From Equation (17):

$$d'_m = 413\ a\ I \text{ sec-ft. per sq. mile} \quad (23)$$

from Equation (19):

$$d'_m = \frac{3\ 200\ a\ R}{\sqrt{t}} \text{ sec-ft. per sq. mile} \quad (24)$$

from which,

$$D_m = 413\ a\ M\ I \text{ sec-ft.} \quad (25)$$

or,

$$D_m = \frac{3\ 200\ a\ M\ R}{\sqrt{t}} \text{ sec-ft.} \quad (26)$$

in which M represents the area of the water-shed, in square miles.

In applying this formula to large areas, it must be remembered that the individual station records of rainfall do not represent intensities as dependably for large areas as they do for small areas. Whenever practicable the relation of the rainfall on the entire water-shed to that of the single station or, better, to the combined records at a number of stations, should be ascertained. This is done by comparing the station records with the rainfall on the whole area, as determined by isohyetose lines.

The factor, R, in the writer's formulas for the maximum rate of run-off, should always represent an average value for the area to which it applies. That is, if the maximum rain to be expected in 1 hour has been determined for numerous places regularly distributed throughout the area, the value of R to be used in the formula will be the mean of all such determinations.

When there is a wide range in the meteorological conditions in the subdivisions of a water-shed (which need not be restricted to only three), and there is a wide range in the values of R and of I in different parts thereof, it may be advisable to use the formulas in a more general form, deduced from Equations (21) and (22). They can then be written:

$$D_m = \frac{3\ 200}{\sqrt{t}} (a_1 M_1 R_1 + a_2 M_2 R_2 + a_3 M_3 R_3) \text{ sec-ft.} \quad (27)$$

or,

$$D_m = 413\ (a_1 M_1 I_1 + a_2 M_2 I_2 + a_3 M_3 I_3) \text{ sec-ft.} \quad (28)$$

in which, as explained, $M_1 + M_2 + M_3 = M$, and all these areas are expressed in square miles.

Due to the fact that the absorption of water by soil or other pervious material, as well as the rate of evaporation, may be regarded as fairly constant, while the average intensity of the rainfall decreases as the time to which the intensity applies increases, the relative effect of perviousness will increase in some measure as the critical time increases. This statement has, of course,

particular application to large water-sheds in which the critical time may be measured by days with occasional cessation of rainfall instead of by minutes and hours, as is the case in urban problems. The coefficient of perviousness, that is, a in the formula for urban areas would better be considered as a run-off coefficient and should decrease as the critical time increases. Bearing in mind that $a = 1$ for small impervious areas, the following expression for a has been found to give results in fair conformity with observed facts:

$$a = \frac{60}{60 + c\sqrt[3]{t}} \quad \ldots\ldots\ldots\

By inserting in Equations (23) to (26), the value of a, Equation (29), and using round numbers, the formulas for maximum run-off are as follows:

$$d'_m = \frac{25\,000\,I}{60 + c\,t^{0.33}} \text{ sec-ft. per sq. mile} \quad \ldots\ldots (30)$$

or,

$$d'_m = \frac{190\,000\,R}{60\,t^{0.5} + c\,t^{0.83}} \text{ sec-ft. per sq. mile} \quad \ldots\ldots (31)$$

and,

$$D_m = \frac{25\,000\,M\,I}{60 + c\,t^{0.33}} \text{ sec-ft.} \quad \ldots\ldots (32)$$

or,

$$D_m = \frac{190\,000\,M\,R}{60\,t^{0.5} + c\,t^{0.83}} \text{ sec-ft.} \quad \ldots\ldots (33)$$

The use of the formula is made convenient by Table 7 and by a diagram, Plate IV. In both Table 7 and Plate IV, the value of the factor is shown which, when multiplied by the maximum rainfall in 1 hour, R, expressed in inches, will give the maximum run-off rate, in second-feet per square mile.

The value of t is determinable, as has been explained, from the topographic features of the water-shed and the character of the storm-water conduits. The value of c will be adopted from known characteristics of the ground surface, with special regard to perviousness.

The formula is based on the assumption that $I = \frac{C}{\sqrt{t}}$ (Equation (1)).

The appearance of I in the formula is not necessary when R appears therein.

It will be seen by inspection of Plate IV, that straight lines substituted for the curves there shown would afford a fairly good approximation to the values given by the formula. A coefficient, which may be called C'', and the exponent of t, will then be subject to selection according to the surface characteristics of the water-shed. The approximation formula for maximum run-off, in second-feet per square mile, may then be written:

$$d'_m = \frac{C'\,R}{t^x} \text{ sec-ft. per sq. mile} \quad \ldots\ldots (34)$$

where,

$C'' = 3\,500$ and $x = 0.5$ for impervious areas;
$C'' = 3\,300$ and $x = 0.6$ for mountainous areas;
$C'' = 3\,000$ and $x = 0.7$ for rolling country;
$C'' = 2\,100$ and $x = 0.75$ for flat country; and
$C'' = 600$ and $x = 0.8$ for sandy regions.

Whenever large areas are under consideration, that is, when maximum stream or river flow, as distinguished from the storm-water flow of urban conduits, is to be determined, the value of R should be estimated from the maximum rainfall in periods of 24 hours or more, rather than from the maximum rainfall in shorter periods.

TABLE 7.—THE VALUE OF THE FACTOR, $C' = \frac{190\,000}{60\,t^{0.5} + c\,t^{0.83}}$, FOR VARIOUS VALUES OF t AND c, IN THE FORMULA, $d'_m = \frac{190\,000\,R}{60\,t^{0.5} + c\,t^{0.83}} = C'R$.

Critical time, t, in minutes.	$c = 0.5$, impervious area, in second-feet.	$c = 5$, mountains, in second-feet.	$c = 20$, rolling country, in second-feet.	$c = 50$, flat country, in second-feet.	$c = 250$, sandy regions, in second-feet.

NOTE.—To find the maximum run-off per square mile in second-feet multiply the figures in Table 7, by the value of R, that is, the maximum rainfall in 1 hour expressed in inches.

To show the effect of area on the maximum stream flow or maximum rate of run-off, areas of similar outline and similar topographical features and subject to the same meteorological conditions may be compared with each other.

Because areas of various extent, but similar in topography and outline, will have values of t fairly proportional to the square root of the surface area, it may be assumed for such areas that,

$$t = K\sqrt{M} \qquad (35)$$

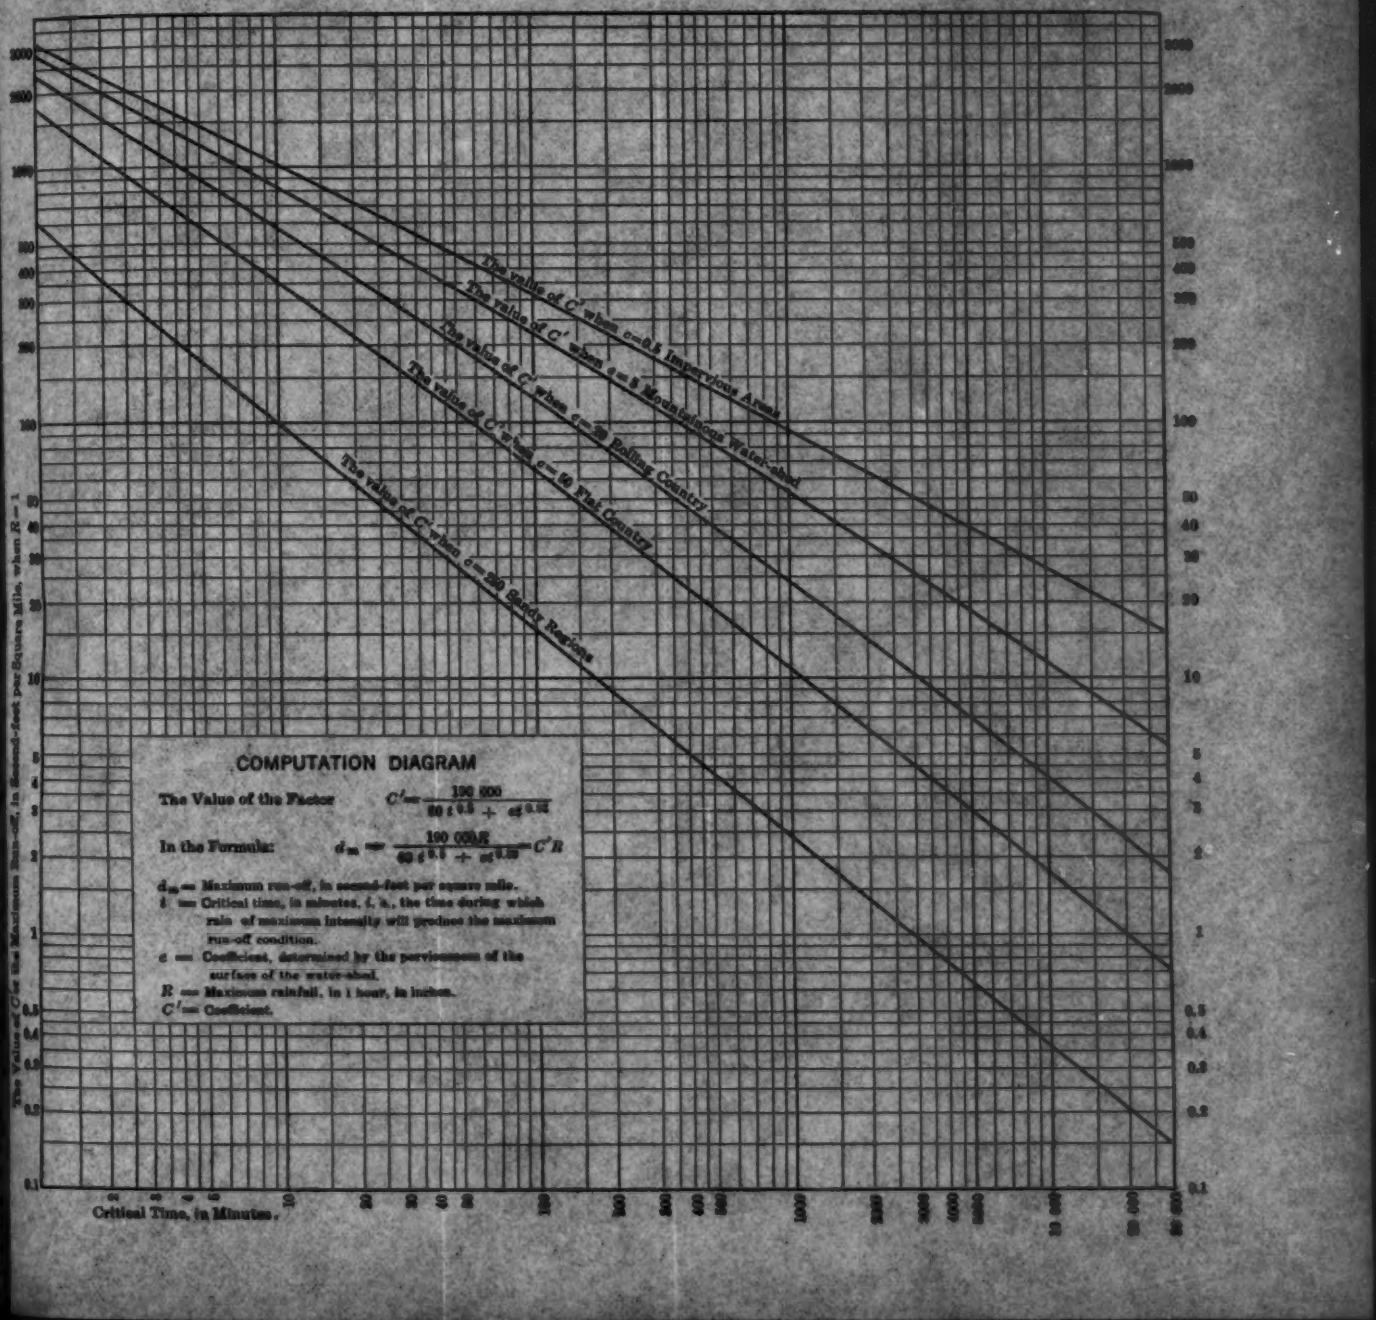
in which K is a coefficient that can be determined for any set of water-sheds complying with the condition of similarity.

Let it now be assumed that for a number of mountain water-sheds of similar characteristics, a value of $K = 20$ has been ascertained. This will make for this special case:

$$t'' = 20\sqrt{M}$$

and from Equation (23),

$$d''_m = \frac{715\,a\,R}{(M)^{\frac{1}{4}}}$$



Mountainous regions being under consideration, there will be:

$$a = \frac{60}{60 + 5\sqrt[3]{t}}$$

Therefore, inserting the value of t'',

$$a = \frac{60}{60 + 14\,M^{0.17}}$$

for the special case only.

COMPUTATION DIAGRAM

The Value of the Factor $C' = \frac{100\,000}{60\,t^{0.5} + ct^{0.25}}$

In the Formula: $d_m = \frac{100\,000\,cR}{60\,t^{0.5} + ct^{0.25}} = C'R$

d_m = Maximum run-off, in second-feet per square mile.
t = Critical time, in minutes, *i. e.*, the time during which rain of maximum intensity will produce the maximum run-off condition.
c = Coefficient, determined by the perviousness of the surface of the water-shed.
R = Maximum rainfall, in 1 hour, in inches.
C' = Coefficient.

The following values, Table 8, result for this special case when water-sheds range in area from 10 to 10 000 sq. miles.

TABLE 8.—Relative Maximum Stream Flow from Similar Mountain Water-sheds of Various Extent.

In this table, R represents maximum rainfall in 1 hour.
(Special case, only, $K = 20$)

Area, in square miles.	Critical time, in minutes.	Maximum flow, in second-feet per square mile.	Total maximum flow, in second-feet.
10	63	802 R	8 000 R
20	89	250 R	4 880 R
50	142	188 R	9 440 R
100	200	149 R	14 700 R
200	283	122 R	24 400 R
300	346	108 R	32 400 R
400	400	99 R	39 600 R
500	450	92 R	46 000 R
1 000	630	75 R	74 000 R
5 000	1 410	44 R	220 000 R
10 000	2 000	34 R	340 000 R

The values in Table 8 show that in all mountainous regions exposed to the same rainfall conditions, the rate of maximum run-off, as determined by the formula, is about nine times greater per square mile from a water-shed having an area of 10 sq. miles and about four to five times greater from 100 sq. miles than from a water-shed having an area of 10 000 sq. miles. In the light of the stream-flow information obtainable from records of the U. S. Geological Survey, and other sources, and the conclusions reached in this matter by other investigators (Fig. 9), this relation appears to be quite reasonable. When account is taken of the fact that the value of R, that is, the maximum rainfall in 1 hour, may be much larger for those spots within the larger area at which the rain storms break with greatest severity, it will be readily seen that the disparities between the maximum run-off rate from the small area and that from the large area, as noted, which are predicated on the same value of R throughout the small area as throughout the larger area, may be considerably exceeded.

Other formulas for the approximation of maximum run-off under extreme conditions of rainfall are numerous. Most of these are intended to serve in restricted territory throughout which a similarity of rainfall conditions permits the use of run-off coefficients which are practically independent of the variations in the intensity of rainfall. Of this type, are the formulas suggested by the late Mr. Kuichling* for the New England and North Atlantic States; the Metcalf and Eddy formula;† the formula used by W. E. Fuller,‡ M. Am. Soc. C. E., and many others. Such formulas will naturally be used with some hesitation until they are supplemented with suitable correction factors to adapt them to meteorological conditions which depart materially

* "Report on the Barge Canal of New York," 1901, Part 14 of the "Report on Water Supply," by Emil Kuichling, p. 844.

† "American Sewerage Practice," by Metcalf and Eddy, p. 251.

‡ *Transactions*, Am. Soc. C. E., Vol. LXXVII (1914), p. 564.

from those which obtain in the regions to which they are intended to apply. All such formulas, nevertheless, indicate in a more or less definite manner the conclusions of various investigators relative to the effect of topography and area on maximum stream flow.

The better type of formula is that in which the maximum stream flow is made a function of the intensity of rainfall as well as the area and topography and the soil or surface conditions of the water-shed. Most of these formulas contain a factor based on the precipitation conditions which will produce maximum run-off. Unfortunately, however, it is not always clear how this factor shall be determined. For comparison, the following formulas are briefly discussed.

A.—Formulas for Maximum Run-Off in Which the Intensity of Rainfall is a Factor.—The Bürkli-Ziegler formula:

$$D_m = C\,I\,M\sqrt[4]{\frac{S}{M}} \text{ sec-ft.} \quad (36)$$

and,

$$d_m = C\,I\sqrt[4]{\frac{S}{M}} \text{ sec-ft. per sq. mile} \quad (37)$$

In this formula, I stands for the maximum intensity of rainfall in some definite time-period, preferably 1 hour. If some other time-period is selected, the effect will be to alter the coefficient, but not the ultimate result.

The McMath formula:

$$D_m = C\,I\,M\sqrt[5]{\frac{S}{M}} \text{ sec-ft.} \quad (38)$$

and

$$d_m = C\,I\sqrt[5]{\frac{S}{M}} \text{ sec-ft. per sq. mile} \quad (39)$$

In this formula, too, I stands for the maximum intensity of rainfall in some definite time-period.

In this formula, and also in the Bürkli-Ziegler formula, the effect of the duration of the critical time-period, which lengthens as area increases, on the average rate of rainfall, and, therefore, on the rate of run-off, is not apparent as the factor, t, does not appear therein. Because this factor has been assumed to bear some more or less definite relation to the area and also to the slope of the water-shed, and as both area and slope appear in the formulas, the possibility that the formulas fairly approximate the most probable law of the variation of maximum run-off rate with area is not excluded.

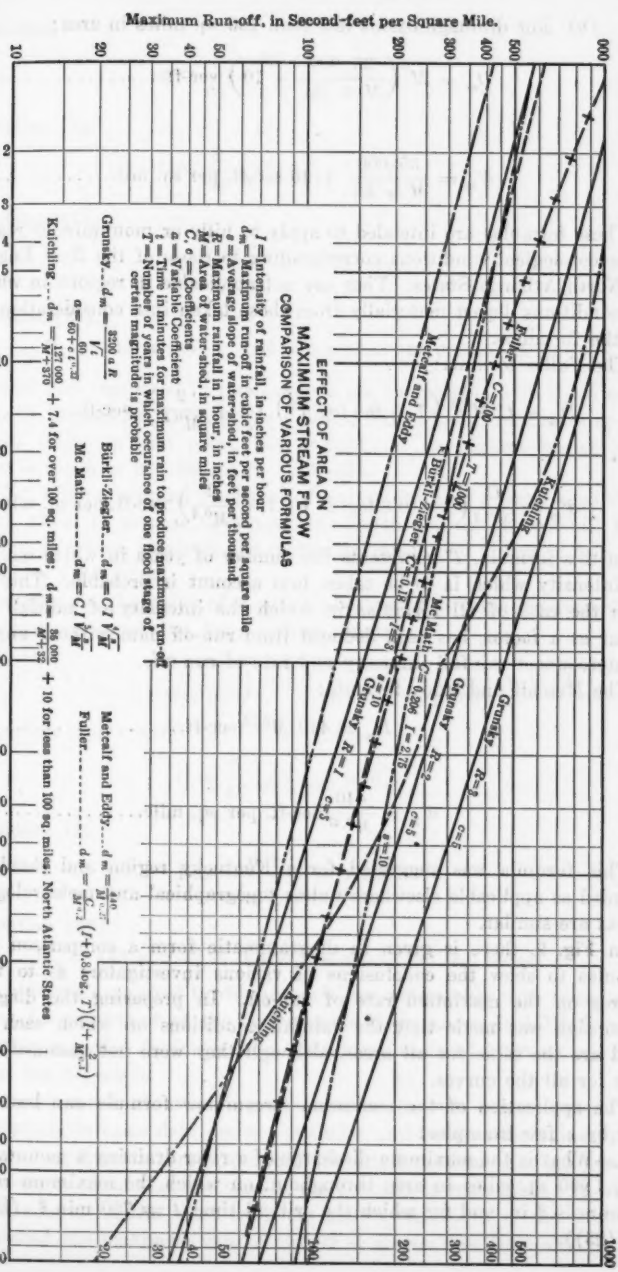
B.—Formulas in Which Intensity of Rainfall Does not Appear as a Factor.—The Kuichling formulas:

(*a*) For drainage basins more than 100 sq. miles in area:

$$D_m = M\left(\frac{127\,000}{M + 370} + 7.4\right) \text{ sec-ft.} \quad (40)$$

and,

$$d'_m = \frac{127\,000}{M + 370} + 7.4 \text{ sec-ft. per sq. mile} \quad (41)$$



Maximum Run-off, in Second-feet per Square Mile.
EFFECT OF AREA ON
MAXIMUM STREAM FLOW
COMPARISON OF VARIOUS FORMULAS
I = Intensity of rainfall, in inches per hour
d_m = Maximum run-off in cubic feet per second per square mile
S = Average slope of water-shed, in feet per thousand
R = Maximum rainfall in 1 hour, in inches
M = Area of water-shed, in square miles
C, c = Coefficients
n = Variable Coefficient
t = Time in minutes for maximum rain to produce maximum run-off
T = Number of years in which occurrence of one flood stage of certain magnitude is probable
Grunsky... $d_m = \frac{3200\ a\ R}{\sqrt{t}}$
$a = \frac{60}{60 + t^{1.32}}$
Kuichling... $d_m = \frac{127\,000}{M + 370} + 7.4$ for over 100 sq. miles; $d_m = \frac{86\,000}{M + 82} + 10$ for less than 100 sq. miles; North Atlantic States
Burkli-Ziegler... $d_m = C\ I\ \sqrt[4]{\frac{S}{M}}$
Mc Math... $d_m = C\ I\ \sqrt[4]{\frac{S}{M}}$
Metcalf and Eddy... $d_m = \frac{440}{M^{0.87}}$
Fuller... $d_m = \frac{C}{M^{0.7}}\ (1 + 0.8 \log. T)\left(1 + \frac{2}{M^{0.7}}\right)$
Area of Water-shed, in Square Miles.

FIG. 9.

(*b*) For drainage basins less than 100 sq. miles in area:

$$D_m = M\left(\frac{35\ 000}{M + 32} + 10\right) \text{ sec-ft.} \quad \ldots\ldots(42)$$

and,

$$d'_m = \frac{35\ 000}{M + 32} + 10 \text{ sec-ft. per sq. mile.} \quad \ldots\ldots(43)$$

These formulas are intended to apply to hilly or mountainous regions and to meteorological conditions corresponding to those of the New England and the North Atlantic States. They are not applicable in regions in which rainfall conditions depart materially from those taken into consideration in shaping the formulas.

The Fuller formula:

$$D_m = C\,M^{0.8}\left(1 + 0.8 \log T'\right)\left(1 + \frac{2}{M^{0.3}}\right) \text{ sec-ft.} \quad \ldots\ldots(44)$$

and,

$$d'_m = \frac{C}{M^{0.2}}\left(1 + 0.8 \log T'\right)\left(1 + \frac{2}{M^{0.3}}\right) \text{ sec-ft. per sq. mile.} \quad \ldots\ldots(45)$$

In this formula, T' represents the number of years in which one storm of the intensity which is to be taken into account is probable. This formula, as in the case of all formulas in which the intensity of rainfall does not appear as a factor, has been deduced from run-off data without any attempt to interconnect rainfall intensity and rate of run-off.

The Metcalf and Eddy formula:

$$D_m = 440\ M^{0.73} \text{ sec-ft.} \quad \ldots\ldots(46)$$

and,

$$d'_m = \frac{440}{M^{0.27}} \text{ sec-ft. per sq. mile.} \quad \ldots\ldots(47)$$

This formula was suggested for a Kentucky region and should not be regarded as applicable elsewhere unless topographical and meteorological conditions are similar.

In Fig. 9, there is given in diagrammatic form a comparison of a few formulas to show the conclusions of various investigators as to the effect of area on the maximum rate of run-off. In preparing the diagram, the assumption was made that the rainfall conditions on which each curve is based are the same for all areas, although they were not assumed to be the same for all the curves.

The application of the maximum stream-flow formula can best be made clear by a few examples:

1.—What is the maximum discharge of a river draining a mountain watershed, 1 900 sq. miles in area throughout, on which the maximum rainfall in 24 hours is 8 in. and for which the critical time, $t = 720$ min.? (See Equation (25)).

In this case,

$$a = \frac{60}{60 + 5\sqrt[4]{720}} = 0.57$$

from Equation (3),

$$C = \frac{8}{24}\sqrt{1\,440} = 12.7$$

from Equation (1),

$$I = \frac{12.7}{\sqrt{720}} = 0.47$$

from Equation (25),

$$D_m = 413 \times 0.57 \times 0.47 \times 1\,900 = 210\,000 \text{ sec-ft.}$$

The conditions suggested in this example are comparable with those which prevail on the American River, above Folsom, Cal., which, from a water-shed of 1 900 sq. miles, at that point, has probably at its highest known stage discharged as much as 200 000 sec-ft. (1861-62).

2.—What is the maximum discharge of a river draining a water-shed three-fourths of which is mountainous and one-fourth rolling or foot-hill land, 9 000 sq. miles in area, in which the maximum rainfall in 2 days is 6 in. and for which $t = 1\,800$ min.?

In this example, the value of a will lie between the value determined for a mountainous area and that for a rolling country:

$$a = \tfrac{3}{4}\left(\frac{60}{60 + 5\sqrt[4]{1\,800}}\right) + \tfrac{1}{4}\left(\frac{60}{60 + 20\sqrt[4]{1\,800}}\right) = 0.42$$

From Equation (3),

$$C = \frac{6}{48}\sqrt{2\,880} = 6.7$$

from Equation (1),

$$I = \frac{6.7}{\sqrt{1\,800}} = 0.158$$

from Equation (25),

$$D_m = 413 \times 0.42 \times 0.158 \times 9\,000 = 247\,000 \text{ sec-ft.}$$

The conditions suggested in this example are comparable with those which prevail in the water-shed of the Sacramento River above Red Bluff, where the maximum recorded discharge from a drainage basin of 9 300 sq. miles has been about 254 000 sec-ft.

There is no need of extending illustrations to still larger water-sheds, because dependable basic data are not available and because the values of the constants and coefficients here introduced are only tentative. Enough has been said, however, to show that the type of the formula is reasonable. It will be found particularly helpful when from the known conditions of the flow from one water-shed, the maximum rate of run-off or stream flow from another with

similar meteorological and rainfall conditions, is to be estimated. It will also be useful in estimating maximum rates of run-off due to rains of extreme intensity when the maximum rates due to rains of less intensity have been ascertained by stream gauging.

When large parts of a water-shed are lake or reservoir surface, especial consideration may have to be given to the retarding effect of storage in the lakes or reservoirs. The retention of water in storage basins reduces the maximum rate of outflow therefrom and, therefore, reduces the peak of the discharge curve for points below the reservoir. Recourse may be necessary to the mass curve in order to determine this effect.*

Evaporation from Water Surface as Affecting Run-Off.

Whenever any considerable proportion of a water-shed is water surface, as when it embraces lakes of considerable extent, it will become necessary to give the water production due to a known quantity of rain especial study. The depletion of the water bodies or the accession of water which they have received from the beginning of one climatic year to the beginning of the next must be taken into account. This may involve a study of the loss of water by evaporation. When the rainfall is light, this loss of water from a lake by evaporation frequently exceeds the accession resulting from rain falling directly on the water. The water production of the lake area under such circumstances is negative. In computing the evaporation from the surface of a lake or reservoir, the following simple relation between mean monthly temperature and the probable average rate at which water is lost by evaporation throughout the month will be found to be helpful. This relation between the mean monthly temperature of the atmosphere and the rate of evaporation is shown in Table 9.

TABLE 9.—Evaporation from Open Water Surface.†

(Based on a revised curve.)

Mean monthly temperature, in degrees Fahrenheit.	Rate of evaporation, in feet per day.	Evaporation per Month:		
		In 28 days. Inches.	In 30 days. Inches.	In 31 days. Inches.
25	0.0015	0.50	0.54	0.56
30	0.0019	0.64	0.68	0.71
35	0.0025	0.84	0.90	0.93
40	0.0033	1.12	1.19	1.22
45	0.0043	1.48	1.55	1.60
50	0.0056	1.88	2.02	2.06
55	0.0073	2.45	2.63	2.71
60	0.0095	3.19	3.42	3.53
65	0.0121	4.06	4.32	4.50
70	0.0151	5.07	5.44	5.62
75	0.0186	6.25	6.70	6.92
80	0.0223	7.50	8.04	8.30
85	0.0260	8.74	9.37	9.68
90	0.0300	10.08	10.80	11.16

It seems to be fairly well established that evaporation increases somewhat with elevation above sea level. In the absence of any conclusive data relating

* *Transactions*, Am. Soc. C. E., Vol. LXI (1908), p. 335.

† *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1968.

to the rate of this increase, the following formula is suggested for use until something better is offered:

$$E = E' + 0.0012 \sqrt{FH} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (48)$$

In this formula, E is the monthly evaporation, in inches, at the place for which evaporation is to be determined, when the altitude of the place is H ft. above sea level; and E' is the monthly evaporation at sea level given in Table 9, which would obtain at the mean monthly temperature of F degrees, noted for any month at the place at which evaporation is to be estimated.

It must not be expected that for any single month evaporation will always be indicated correctly by the evaporation curve. Owing to the great variation in conditions of wind, humidity, sunshine, and the daily range of temperature, there may be wide departures from the monthly evaporation rate which the curve indicates as the probable rate. For 12 months, the probable error is much less than for any single month. The curve is intended for use when the annual evaporation is to be determined.

DISCUSSION

DANA M. WOOD,* M. AM. SOC. C. E. (by letter).—Engineers are still divided in their opinion regarding the advisability of publishing rainfall and run-off statistics for the calendar year or for some universally adopted climatic year. A committee of the Boston Society of Civil Engineers (the Run-Off Committee) sent out questionnaires to many engineers, asking their opinions on this question, and the replies were divided about equally. Many seemed to feel that particular studies in a specific locality might require the use of the climatic year, but opinion differed as to the best common climatic year to use, varying as it does in different parts of the United States.

The advantage in adhering to the calendar year for rainfall and run-off statistics appears to be threefold: (1) because of the non-uniformity of the climatic year; (2) it is the method used by the U. S. Weather Bureau in publishing the mass of rainfall figures already available, and the difficulties in bringing about a change, including a revision of past publications, would seem to be insurmountable for the present at least; and (3) the business reports of most municipalities and companies are on a calendar-year basis, and these reports often contain statistics of the nature discussed. The argument may sound like that of "locking the barn door after the horse is stolen" but, nevertheless, it is real. It is difficult to change long-established practice, even to substitute improved methods.

In regard to run-off records, engineers seem to be very definitely committed to the climatic year beginning October 1st, by the adoption of this system by the Water Resources Branch of the U. S. Geological Survey. The chief argument in favor of its general adoption seems to be that it permits of the continuous uninterrupted investigation of winter-flow conditions in those localities subject to ice conditions, and of the office preparation of report data at times of the year when field work is not so necessary; even this is not strictly true for all localities. The argument that it permits the issuance of published reports six months earlier than would otherwise be possible, does not seem to have so much force in recent years.

Summing up, it appears to matter little to the individual engineer which system is used because, in the majority of cases, he is forced to make his own transpositions and calculations on the basis of what in his judgment is the best division of the year for the locality he is studying. As long as the diversity of opinion exists, every one cannot be entirely satisfied, and the only satisfactory solution would be to use different divisions of the year for different sections of the country, and this also has its objections.

Referring to the discussion of "Rainfall in the Climatic Year", the question arises as to what is a normal rainfall. According to Weather Bureau data, the annual normal is the sum of the normals for all the months, and the normal for each month is the average for the period of record. Furthermore, normals are computed at stipulated intervals and are not always changed between times to obtain the correct figure to date.

* Engr., Stone and Webster, Incorporated, Boston, Mass.

Attention has been called to the value of the median.* In the paper, the study of frequency might be made theoretically more correct by the use of the median, but it is admitted that the final conclusions would be practically the same in this case, because there is so little departure between the two for the records used. Fig. 5 indicates this; but it is often not the case in other localities.

At the risk of repeating Mr. Grunsky's arguments, emphasis should be laid on the fact that, regardless of any arbitrary division of the year, the precipitation in the few months previous to the new year has a marked effect on ground-water levels and, therefore, on run-off. In other words, any method of analysis depending on the determination of the ratio of run-off to rainfall in any one given month will lead to wrong conclusions. Such ratios are of value for seasonal variations, but the length and dates of the several seasons will vary from year to year.

A fairly reliable estimate of the probable average, minimum, and maximum annual rainfall can be made for a given water-shed by the methods given in the paper. Other excellent papers indicate somewhat different methods for the same purpose.

In making estimates of the power available in a given water-shed, most engineers now desire both a hydrograph and a duration-of-flow curve, the latter including both the extreme maximum and minimum flows of record. If the annual run-off for the three typical years can be determined from rainfall statistics, the question of its relative distribution throughout the year is still to be determined.

So many different factors affect run-off that even with the same rainfall, in two different years, the run-off may be quite different both in quantity and distribution. The condition of the ground-water storage is an important factor, as well as other factors pointed out in the paper.

In order to determine the probabilities regarding run-off, some information which covers actual stream-flow measurements, even if for a short term of years, is imperative.

For a number of years the writer has intermittently been collecting and comparing run-off records compiled by a method similar to that used by Mr. Grunsky for rainfall records.

Duration curves of flow for the three types of years mentioned furnish a starting point. Discussing the average duration curve only in that which follows, the basis for comparison is always taken as the time scale, using it as percentage of total time for the period covered by the records and comparing flows for every 5% of the time. The flow is expressed as a percentage or ratio of the normal flow, the normal flow being taken as either the average or the median as may best suit the investigator's ideas on that subject.†

The value in using such a method lies in the comparisons afforded between what to the casual observer are entirely unlike streams. Records can be compared for widely different sizes of water-shed and for widely different annual run-offs; it is the relative distribution which is being studied.

* *Engineering News-Record*, Vol. 80, p. 628.

† *Stone and Webster Journal*, February, 1917.

This naturally brings out the possibilities of classing streams as to their drainage-basin type, with or without varying degrees of storage development, etc. Of course, there are many gradual gradations from one class to another. This is true, also, for the classifications given by Mr. Grunsky, as it is necessary sometimes to adopt a value between those given.

In accordance with the writer's method, comparisons should be, as in rainfall studies, for the same period of years, but short-term records can be extended to long-term records just as readily as with rainfall records.

Studies along these lines have not been made to a sufficient extent to determine the full possibilities of the method and a classification system; but as an indication, Tables 10, 11, and 12 are given, covering several records analyzed in the foregoing manner. With such variations in actual stream-flow records in a restricted locality, as shown by these tables, the dangers of relying entirely on rainfall records are obvious.

Table 12 does not furnish an absolute comparison between records because the time-period is variable. It does show how several types of streams vary in run-off distribution. Extreme cases are selected.

The lengths of the records are as follows:

Column (2), 1878-1915 = 38 years, average flow = 0.538 cu. ft. per sec. per sq. mile.

Column (3), 1912-1916 = 5 years, average flow = 1.724 cu. ft. per sec. per sq. mile.

Column (4), October, 1905-August, 1917 = 12 years, average flow = 1.63 cu. ft. per sec. per sq. mile.

Column (5), October, 1903-September 1920 = 17 years, average flow = 2.19 cu. ft. per sec. per sq. mile.

Column (6), October, 1912-September, 1920 = 8 years, average flow = 1.61 cu. ft. per sec. per sq. mile.

Column (7), October, 1904-September, 1920 = 16 years, average flow = 1.68 cu. ft. per sec. per sq. mile.

Column (8), October, 1880-September, 1920 = 40 years, average flow = 1.51 cu. ft. per sec. per sq. mile.

Column (9), October, 1905-September, 1920 = 15 years, average flow = 1.63 cu. ft. per sec. per sq. mile.

Column (10), October, 1887-September, 1920 = 33 years, average flow = 1.50 cu. ft. per sec. per sq. mile.

† Controlled by plant above.

To study the monthly variations, it has been the writer's custom to prepare the duration-of-flow table so that duration-of-flow curves for each month can be also prepared. Obviously, the median for each month may be utilized in studying normal seasonal variations, and the duration curves indicate monthly extremes.

This general method can and has been used for obtaining a flow-duration curve where the run-off records are meager. Working from the rainfall to the estimated run-off for a given type of year, the distribution of this annual can be assumed in accordance with that in neighboring or similar basins for which there are reliable run-off records. If short-term records are available on the stream under investigation, the relative distribution for the period covered can be compared with that of other streams for the same period, and a neighboring record selected showing similar characteristics. From these data, an estimated curve for the longer period of years can be obtained, as described for the rainfall records.

* Controlled flow.

Maximum and minimum probable daily run-off estimates can be made along the lines suggested, but such results should always be checked against determinations made by other methods and the most reasonable value adopted, unless reliable long-term flow records are available near-by.

The purpose of this discussion has been to offer additional suggestions which may prove helpful in what is at best a very difficult and uncertain problem. Changes in run-off régime, as in rainfall, are abrupt, and result from many factors operating some against, some with, each other. In the last analysis, only general tendencies or types of years can be predicted and, even after the most intensive study, departure from the expected will be encountered.

In conclusion, the writer feels that even with the relatively short-term run-off records available in the West, streams with long-term records can be found elsewhere, which will furnish a basis for extending the short-term record. Results obtained in this manner should furnish an excellent checks on determinations made entirely from rainfall data.

C. F. MARVIN,* ESQ. (by letter).—On behalf of the U. S. Weather Bureau the writer may state that Mr. Grunsky's request for a change in the annual publication of meteorological data, in that the annual summaries should apply, throughout the whole country, to a climatic year and not to a calendar year, was received and considered in a sympathetic manner. Shortly after its receipt, letters requesting expressions of views on the subject-matter therein were sent to various persons and organizations. The response has not been as full and satisfactory as could be desired, and, therefore, a second inquiry and questionnaire is being distributed to recipients of the *Monthly Weather Review,* in the hope that discussion on this important proposition will be stimulated.

As Mr. Grunsky's request appears to have been based mostly on the needs of students of rainfall in California, it has been thought desirable to secure a wide expression of views, and, therefore, correspondence and discussion on the subject, on the part of engineers, are solicited by the Weather Bureau.

RUDOLPH HERING,† M. AM. SOC. C. E.—The question of rainfall and run-off studies has been before engineers for a great many years. About forty years ago, when the speaker had to face the problem for the first time seriously, it seemed almost hopeless to obtain what an engineer likes—exactness—some formula on which one could positively rely. About that time, the speaker was also confronted with the use of formulas for similar physical data as aids in the solution of problems, and it sometimes seemed hopeless to use formulas for any series of occurrences.

This remark was once made about some pile-driving experience to the editor of *Engineering News,* who requested something about that particular subject for publication, which information was subsequently furnished him. This was in regard to the Fairmount Bridge in Philadelphia, Pa. There was trouble about the piling, and the question arose as to whether or not the engineer could be sure that the pile was going to hold up the weight to be placed on it when driven with a certain weight of hammer and a certain distance of fall. The speaker began to collect all the formulas available in America, England, France, and Germany on the subject, with the thought of finding out what those various formulas really meant. A heavy and a light hammer and a high and a low fall were assumed and the results were worked out. These results were published in *Engineering News* (1889), and the late Arthur M. Wellington, M. Am. Soc. C. E., one of the editors, deduced afterward from those formulas the one now known as the Wellington formula.

Gen. McAlpine deduced the formula known as the McAlpine formula from experiments made in the Brooklyn Navy Yard. He gave it to the world

* Chf., U. S. Weather Bureau, Washington, D. C.
† Cons. Engr., New York City.

without any limitations, and it was used by engineers. It will be seen from that article in *Engineering News,* assuming a possible case of pile-driving, that the more the pile was pounded the less it would carry; in other words, the result was negative.

Now, of what use is such a formula? In fact, many formulas are questionable. The speaker has suggested that every one offering a formula should do so as in calculus, when the two limits to the integral sign are given, meaning that this formula is applicable within those limits and is no good outside of them.

One reason why Kutter's formula interested the speaker was because it comprised all cases from a 1-in. pipe to the Mississippi River. All the gaugings used were between those two limits, and the formula works astonishingly well under all circumstances if the coefficient of roughness is judged correctly.

This shows that the use of a formula by a practical engineer is somewhat dangerous, unless he knows the data from which the formula has been derived. In that case, of course, engineers have no better guide than a formula, because it practically gives them a curve between known facts, and is safe to use; beyond that, it is not safe.

Another case was published about 1878.* There was a discussion on the same subject as that presented by the author, and a formula for run-off was given. It was shown in the discussion how easy it was to obtain absurd results; and the speaker presented another method of getting those results, namely, by plotting curves from actual gaugings under different conditions. It was felt that those limited curves which were established from known facts, would always be reliable, whereas a formula representing a curve of perhaps infinite length, might lead to great error. Data had been collected of the run-off for many streams in America, Europe, and India, where heavy rain storms and floods occur, giving the maximum flood discharges down to small areas, such as the municipal engineer finds in sewerage problems.

Engineers should feel grateful to Mr. Grunsky for having compiled so many data and made such a thorough study of a very important subject which in the collection of data has by no means as yet been exhausted. He has given sufficient information to permit an engineer to proceed with more confidence in the results than without it.

In the Philadelphia Water Department, from 1883 to 1886, some experiments were made with some reference to this subject. The streams were gauged with automatically registering gauges. Not only was the total rainfall measured, but there was also automatic continuous registration. After the speaker left that Department, 36 years ago, these observations were continued, and if the data were properly compiled, they would furnish an unusual amount of information of the run-offs from areas of different topography varying from 100 to 400 sq. miles, extending over a period of from 25 to 30 years. The areas differed in their physical character, some being hilly and some flat; some were much wooded, and others were open agricultural districts.

In order to be able to interpret intelligently these run-offs, with the permission of the Chief Engineer of the Department, the late William Ludlow,

* *Proceedings,* Engrs. Club of Philadelphia, Vol. 1 (1880), p. 146 *et seq.*

M. Am. Soc. C. E., a few acres of land—about half a dozen—with different physical characteristics were staked off. For instance, one was very steep and wooded, another steep but plowed agricultural land; then, again, there was a very flat area wooded and one that was open.

The rain was measured in a centrally placed gauge, and the run-off was measured by a water meter placed at the foot of the area, so that it made an interesting and valuable comparison. The results were never published, and the speaker does not know what became of them, but the original data must still be in the files of the Philadelphia Water Department.

Surveys were made of more than 400 sq. miles, and all the wooded and open areas, roads, and even every house in the area, were located, so that its physical character could be determined very closely. Topography over the whole area was taken with 10-ft. contour intervals. Therefore, data for a very interesting study of run-off may be found there recorded.

OLIN H. LANDRETH,* M. AM. SOC. C. E.—The membership of the Society, and the Profession at large, are under great obligations to Mr. Grunsky for his repeated valuable contributions to the technical literature on hydrology, including this interesting and valuable undertaking to derive empirical rules relating to rainfall and run-off on the Pacific Slope.

In referring to the fact that the ratio of run-off to rainfall is greater on high mountainous areas than at low altitudes, the author attributes the difference, not to "the character of the surface of the water-shed", but rather to the smaller loss from evaporation in high mountainous areas, due to the lower temperature, and, consequently, the greater proportion of rainfall remaining as run-off.

The fact is not questioned that a greater ratio of run-off to rainfall prevails in high altitudes than in low altitudes, nor is it doubted that the smaller loss from evaporation in the higher altitudes constitutes the main, if not the only, cause of this difference; but, perhaps, it may be questioned whether the lower temperature in mountainous altitudes is the only cause for the reduced loss from evaporation.

In general, evaporation per unit of superficial area from the free surface of water and, at much lower rates, from the surface of snow and ice, mainly depends on, and varies with, three elements: (1) the temperature of the evaporating surface or film; (2) the humidity and the degree of agitation of the air above the evaporation surface; and (3) the length of time of exposure to evaporation. If, instead of a free water surface, the evaporation is from the surface of soil supplied with moisture from ground-water, an additional factor also affects the evaporation rate, namely, (4) the rate at which water is drawn up to the ground surface by soil transpiration, which, in turn, depends on the minimum transpiration capacity of the soil for a unit of depth, and also on the depth of the ground-water below the surface of the soil.

At high mountainous altitudes not only are temperatures generally lower than on the lower plain areas, but the average time of exposure to evapora-

* New York City.

tion is also less, because of the average steeper slopes and resulting higher velocities, both for the free running water and for the ground-water moving down the slopes by percolation.

The average time of exposure to evaporation should vary approximately inversely as the square root of the slope. Thus, with other controlling elements the same, but with comparative slopes of 2° and 8°, respectively, the latter should give average times of exposure to evaporation about one-half those of the former, and as evaporation varies directly with the time of exposure, the evaporation should be about one-half as much on the steeper as on the flatter slope. Also, the generally greater coarseness of soil grains on mountainous areas, as compared with flat areas, favors a more rapid rate of percolation of ground-water and, therefore, still further tends to shorter times of exposure and consequent smaller evaporation loss.

In addition, even with equal temperatures, the evaporation loss from the ground surface should be less on mountainous than on lower plain areas, due to the lesser capillarity and, therefore, lesser transpiration capacity of the coarser mountain soils, as compared with the finer grained soils of the lowlands.

From the foregoing, it would appear that the generally lower temperatures in mountainous areas should not be assumed to be the only cause of the observed lower evaporation losses, but rather that the differences in average slopes and in average soil fineness should be recognized as playing parts—and, perhaps, important parts—in causing the smaller evaporation losses in mountainous as compared with low-level areas.

If this is true, then the desirability should evidently be considered of modifying Equations (13) and (14), which are offered by the author as means of predicting the run-off in mountainous regions from that at low altitudes. These equations at present contain only one factor to account for the difference in run-off, namely, f, the mean temperature throughout the water-shed in question during the "wet season" from December to May.

If, however, it should be decided not to modify the present form of Equations (13) and (14), then, notwithstanding the factor, f, is still retained and used in its defined meaning, the empirical coefficient, C, when evaluated from a sufficiently wide range of observations on the rainfall, P, and on r and r', the run-off from the low-level and mountainous areas, respectively, will inevitably contain the effect of all the elements which really cause the observed difference in the ratio of run-off to rainfall in the high and low areas, respectively, even though no terms are introduced into the equations to represent such other elements than temperature.

THADDEUS MERRIMAN,* M. AM. SOC. C. E.—The papers presented by Mr. Grunsky and by Messrs. Munn and Savage, illustrate two of the prevailing methods used in the study of flood magnitudes. In the first method a formula is deduced to express the maximum flood discharge in its relation to the intensity of the rainfall and the physical features of the water-shed. The second, premising an observed maximum flood discharge, recognizes the possibility of the occurrence of a still greater flood and increases the observed values in some

* Chf. Engr., Board of Water Supply, New York City.

definite proportion, as by assuming an increase in the total run-off and then working backward for the purpose of determining the probable peak discharge. The first of these lines of thought has been well set forth by Mr. Grunsky and the second by Messrs. Munn and Savage. A third method which is perhaps the one most commonly used, consists in plotting observed maximum flood discharges with respect to the area of the drainage basins on which they occurred. An expression is then determined which will enclose, and yet fairly represent, the plotted points.

Each of these three methods constitutes a perfectly legitimate way of approximating the truth, but only the second stresses the fact, which the speaker considers to be of great importance, that greater floods than any which have been observed may occur at any time. No formula or expression for flood discharge can be used implicitly as it is written. Allowance always must be made for the case which the formula does not include.

The one outstanding feature in any tabulation of recorded floods seems to be that most of them have occurred in recent years. In a tabulation which lists 274 floods in the United States, 219 have occurred since 1890, and evidently most of them are far from being possible maxima. Obviously, this does not mean that more floods have actually occurred in recent years, but is simply the result of the absence of long-time records.

In 1914, the speaker visited the Ohio region which had been desolated by the floods of March in that year. He then became much interested in this question of probable maximum flood magnitude and has given it a great deal of thought and study. This matter is one of great moment. Our cities, day by day, are spreading wider and farther over the flood-plains of the rivers on the banks of which they were originally founded. The buildings, bridges, fences, and other structures operate to obstruct the free discharge of the flood waters and, where the flood-plain is covered, the greatest damage occurs along the line of greatest resistance. This line of greatest resistance, unfortunately, often lies within the city and accounts for the appalling devastation which has come to be a rather common occurrence. Immediately after such a flood, the newspapers carry large headlines describing it as "unprecedented", "of a magnitude never before known" and as "a wall of water which swept everything before it". After a brief lapse, when the toll of the dead and the missing has been taken, the occurrence is promptly forgotten. Only in those cities which were the actual sufferers do the people live in the fear of another similar occurrence.

It is not necessary to look far to note that practically all sections of the United States are subject to a flood hazard. The records of the very recent past clearly demonstrate this and within the past 20 years "unprecedented" floods have occurred in New Jersey, New York, Pennsylvania, Ohio, Indiana, Iowa, North Carolina, Tennessee, South Carolina, Texas, Colorado, Arizona, and perhaps, the most remarkable of all in regard to volume, occurred at Monterey, Mexico. The list might be extended, but emphasis would not be gained thereby.

Each new flood is "unprecedented" simply because the records are meager and cover a period too short to be of great value. The importance of a flood in

this day and generation is measured by the destruction which it occasions, whereas a flood of equal magnitude, fifty or seventy years ago, might easily have passed unnoticed and unrecorded. When one of these "unprecedented" floods does occur, the newspapers and subsequent technical reports record the failure of one or more dams due to inadequate spillway capacity. Most dams are designed with a factor of safety of about two, but very few spillways are designed with any factor of safety; in many instances, they are made merely large enough to pass the greatest flood of record in the particular vicinity of the dam, or are proportioned on the basis of a formula and no allowance is made for the occurrence of a flood greater than those on which the formula was based.

In view of the generally unsatisfactory knowledge respecting flood magnitudes, the speaker desires to urge the necessity of providing ample spillway capacity on all dams, wherever they may be built, and as a guide to the possible maximum flood, that greater dependence be placed on the observable physical features of the flood-plains of the river itself than on any records of flood discharge which are now available or will become available for many years. By the observable physical features of the flood-plains of the river itself, the speaker refers to those evidences which a flood always leaves. He does not, however, allude to the ordinary high-water drift of logs, etc., which is ephemeral, but refers to those relatively permanent and definite evidences in the deposits of sand and gravel found on the flood-plains near the points where tributary streams first emerge on the flood-plain of the main river valley. When a river is in flood and its flood-plain is covered, the tributary streams flowing at a relatively high velocity are suddenly checked when they enter the comparatively quiet water over the flood-plain. At these points their burden of sand and gravel is deposited in the form of flat topped banks or terraces, the tops of which are only a little below the high-water level in the main stream. Later, these banks may be more or less eroded as the flood subsides and the tributary flows over and scours out the material previously deposited. A study of these evidences is of the nature of a geological investigation with respect to the recent valley deposits and will disclose the heights at which flood waters in the valley have stood at some time in the past. In this manner, the records can be carried back farther than by any other method of which the speaker is aware. He has seen gravel banks of this nature on the Miami River, which were deposited during the flood of 1914, and the tops of these banks are definite and permanent marks of the height at which the flood waters stood in that year. He also has seen similar deposits in North Carolina at elevations above those reached by the great flood of 1916, which flood at certain points raised the previous maximum stage from 21 to more than 42 ft.

Those who are located within the area which was covered with ice during the glacial period have relatively few opportunities for making such studies. In these glaciated areas, it is generally very difficult to distinguish clearly between the deposits of the glacial age and those of comparatively recent formation. Therefore, the suggestion is made that other members of the Society, located in unglaciated areas, by a study of these features, may be able to add greatly to the present imperfect knowledge respecting probable maximum flood heights.

R. A. HILL,* ASSOC. M. AM. SOC. C. E. (by letter).—A method somewhat similar to that described by Mr. Grunsky was developed by the writer to determine the probable rainfall on the mountains between the Southern California valleys and the deserts which lie back of them. The topography of that section of California south of the Tehachipi Mountains is characterized by high ranges which roughly parallel the coast at a distance back of from 40 to 80 miles and which rise out of a plain generally less than 1 000 ft. above sea level. Several of the peaks are more than 10 000 ft. in elevation, although the crests of these ranges are, in general, at elevations of from 5 000 to 8 000 ft. Twenty miles across the mountains from the highly developed coastal valleys lie the Mojave and Colorado Deserts.

The average rainfall per season, in the coastal valleys, is about 16 in. On the ocean side of the mountain ranges, the precipitation increases very rapidly for increases in elevation, up to about 5 000 ft. Above that point, the rate of increase is small, and, as pointed out by the author, there is an apparent decrease for the last few hundred feet below the crest. The rainfall, including snowfall, at or near the crest, is approximately twice as great as in the valleys a few miles below. On the desert side of the crest, the rainfall decreases rapidly and at the same elevation as the coastal valleys, only about one-quarter as much rain falls in any season.

The direction of the storms is usually from the southwest, off the Pacific Ocean. The irregular crest line and the high peaks close to the ocean side cause very definite rain shadows.

An excellent example of this is found near the top of the San Bernardino Mountains in the vicinity of Big Bear and Baldwin Lakes. The precipitation averages about 32 in. per season at the dam at the west end of Big Bear Lake (Elevation 6 500), whereas 5 miles distant at the east end of the lake, the rainfall is about 21 in. per season. At Baldwin Lake, which lies about 4 miles still farther east at about the same elevation, the rainfall is about 16 in. per season. This rain shadow is caused by the high peaks of the San Bernardino and San Gorgonio Mountains and the connecting ridge, all of which are over an elevation of 10 000 ft. and intercept the storms from the ocean. The west end of Big Bear Lake, however, is clear of the shadow of these higher mountains.

The scarcity and the relatively short duration of records of precipitation gave rise to a method quite similar to that described by the author. Instead of determining the mean for the period available and comparing that with the same period at the base station to ascertain the ratio between the rainfalls at the primary and secondary stations, this ratio was determined for each season. The long record of the rainfall at San Bernardino (1870 to date) and the geographic position of that city made it desirable to refer all other stations to it.

Accordingly, with the rainfall each season at San Bernardino as a base, the rainfall for the same season at all other available stations along and back of these mountain ranges was computed as a percentage of that at San Bernardino. These points, several hundred in number, were then plotted with

elevations as ordinates and percentages of the rainfall at San Bernardino as abscissas. There was considerable fluctuation in the points, as was to be expected from the widely variant conditions which exist over these mountains. Curves drawn through the weighted centers of these points gave much the same result as if the ratio between the means had been taken in the first place.

The resulting wing-shaped diagram (Fig. 10), fits quite satisfactorily the conditions known to exist on the ocean and desert sides of the mountains of Southern California. Table 13 gives the results of such comparisons for some

TABLE 13.—RAINFALL OF SOUTHERN CALIFORNIA STATIONS AS COMPARED TO SAN BERNARDINO.

of the typical stations used in developing the diagram. Therefore, it can be assumed, inductively, that the use of this diagram would give reasonable values for the rainfall across these mountain ranges of varying crest height. Several reservoirs for power and irrigation have been constructed on top of these mountains, and in the determination of the feasibility of others projected, this diagram has been of considerable value as an index of the probable water supply from drainage areas with these variable characteristics as to precipitation conditions.

KENNETH ALLEN,* M. AM. SOC. C. E. (by letter).—The author's comprehensive survey of the whole question of rainfall and run-off is a valuable contribution to the already voluminous literature on the subject. Relative to sewer design, to which this discussion is confined, a lamentable lack of uniformity in practice still exists, particularly with regard to run-off, an indication that certain elements in the computations are interpreted differently or are accepted with hesitation in the absence of complete fundamental data.

For an intensity formula, the expression, $I = \frac{C}{t^{\frac{1}{2}}}$, is recommended, and there is much to be said in its favor because of its simplicity and its fair accordance with observed results; but the writer believes that where long-time gaugings are available, modifications of this formula will often show a closer agreement with the curve plotted from gaugings.

The long series of self-registered gaugings at Central Park, New York City, covering 51 years, give an admirable opportunity for arriving at the

* San. Engr., Office of Chf. Engr., Board of Estimate and Apportionment, New York City.

probable frequency of different intensities, and the writer has attempted this by a method which is described in *Engineering News-Record* of April 7th, 1921.* Approximate formulas for the resulting curves shown in Fig. 11 are as follows:†

$$\text{5-year curve} \ldots\ldots I = \frac{25}{(t+4)^{0.67}}$$

$$\text{10-} \quad \text{“} \quad \text{“} \quad \ldots\ldots I = \frac{43}{(t+8)^{0.75}}$$

$$\text{15-} \quad \text{“} \quad \text{“} \quad \ldots\ldots I = \frac{47}{(t+8)^{0.75}}$$

$$\text{25-} \quad \text{“} \quad \text{“} \quad \ldots\ldots I = \frac{78}{(t+11)^{0.84}}$$

$$\text{50-} \quad \text{“} \quad \text{“} \quad \ldots\ldots I = \frac{186}{(t+17)}$$

$$\text{100-} \quad \text{“} \quad \text{“} \quad \ldots\ldots I = \frac{354}{(t+24)^{1.1}}$$

$$\text{Absolute maximum curve} \ldots I = \frac{74\,000}{(t+80)^2}$$

In Table 1, the author gives a comparison between his proposed "parabolic formula" and the "New York formula".‡ Table 14 is a comparison of these formulas with those determined by the foregoing formula for 10 and 15-year frequencies, and is confined for the most part to values of t used in sewer computations.

TABLE 14.—RAIN INTENSITY, IN INCHES PER HOUR.

t.	Brooklyn formula.	Parabolic formula.	10-year New York formula.	15-year New York formula.
5	6.0	6.5	6.28	6.86

120	1.07	1.32	1.13	1.24
720	0.20	0.54	0.31	0.34

The writer believes that the coefficients for run-off in general use should not receive the confidence which they are accorded, and has been unable to discover

* Also referred to on p. 95.

† Suggested by Prof. Edward S. Allen, State College, Ames, Iowa, who sends the following more precise formulas for the 10 and 15-year curves:

$$\text{10-year} \ldots I = 27\, t^{-\frac{1}{2}} 20\, e^{-\frac{1}{2}t}\, t^{-\frac{1}{2}}$$

$$\text{15-year} \ldots I = 30\, t^{-\frac{1}{2}} - 32\, e^{-0.1\, t}\, t^{-1.1}$$

‡ The author's use of the term, "New York Formula", for $I = \frac{150}{t+20}$, is not strictly correct. Heretofore, each of the five Boroughs of the city has used its individual formula, and the foregoing formula adopted by the Borough of Brooklyn many years ago, is used by that Borough only. After studies resulting in a report of the Committee on Rainfall and Run-off of the Municipal Engineers of the City of New York and published in its *Proceedings*, for 1913, the Borough of Manhattan adopted the 10-year formula there proposed, namely, $I = \frac{150}{t+16}$, but, in its application, t is taken to exclude the 4-min. inlet time which is added to the 16 min., giving it the form of the Brooklyn formula, but with a different value for t. In this manner, the two Boroughs were inadvertably mentioned by the writer as using the same formula in his discussion of the paper by L. Standish Hall, Assoc. M. Am. Soc. C. E., in *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 232.

FIG. 11.

many recorded experiments for determining the percentage of run-off from areas of a single character. Although there is a general consensus of opinion among engineers as to run-off factors suitable for adoption, it is a question whether these have not been adopted from precedent rather than from knowledge. Mr. Grunsky has well said that "the effect of this perviousness must be made by the engineer, on the basis of experience."

Of the various elements entering into the determination of R from which erroneous results may be derived, the time of concentration and the gauging of the flow in the sewer are all important. Reliable information regarding the velocity of flow over different surfaces and along gutters is lamentably lacking, so that in practice the inlet time assumed is largely a matter of conjecture. Under urban conditions the error due to this is not often serious but, unless great care is taken, there are possibilities of serious errors in the computations of flow in the sewer, as any competent engineer knows.

Weirs are costly and difficult to introduce and the collection of débris may invalidate the results unless they are constantly under supervision; whereas dependence on computation by a formula may lead to serious error by varying hydraulic conditions, the selection of an improper friction coefficient, the assumption of the grades shown on construction plans instead of those which exist, and the complications introduced by sludge deposits, melting snow, bends, junctions, volume of domestic sewage, surface slope, the hydraulic effect of conditions above and below the section under consideration, etc. The fact that more than 100% run-off is frequently shown in tabulated results is an indication that errors of the nature mentioned have been introduced.

The writer has recently had occasion to study the proper run-off factor for use under completely developed urban conditions and has made inquiry into the practice of various municipalities. Among those questioned there was quite a general agreement with percentages ranging roughly from 75 to 90 per cent.

Attention has been called recently to a number of densely built-up districts in a large city where the capacities of the main trunk sewers are only from 33 to 44% of those required for a 100% run-off and where no complaints of flooding have ever been received. This, of course, does not mean that these sewers were never surcharged, but the question at once arises: Why provide for 80% run-off if 40% answers every purpose?

The writer does not wish to appear as an advocate of the lower coefficients, but mentions this as an argument for more complete and reliable investigations than are now recorded and in such detail as to be entirely convincing.

The economical importance in the use of a proper run-off factor is obvious. Much of the cost of the sewer depends on whether a factor of 40, 60, or 80% is chosen and in a large district an expenditure of several hundred thousand dollars may depend on the selection. Any coefficient based on population density, although applicable in a general way for densities up to 100 per acre, as shown in Table 5, would be impracticable for such developments as obtain in the four cases previously cited, some of which house very large day, in addition to resident, populations.

To summarize, it is believed that although many experiments have been made to determine run-off, the published results usually fail to show that various possible causes of error have been eliminated and indicate that there is need of more definite and reliable data regarding the proper run-off factors for areas of different types. Gaugings are costly and must be maintained for long periods and planned with great care. For these reasons, few municipalities undertake them, and it is submitted whether, in view of its importance and general nature, it would not be an appropriate investigation to be taken up by the Federal Government.

L. STANDISH HALL,* ASSOC. M. AM. SOC. C. E. (by letter).—The author has presented many valuable data and formulas connected with rainfall and run-off studies, but only that part of the paper which deals with the relation between annual rainfall and run-off will be discussed.

The writer has been especially interested in the curve in Fig. 4, which shows the frequency of wet and dry years based on the combined records of rainfall at San Francisco and Sacramento, Cal. In presenting data of this nature, their value can be greatly increased if the coefficient of variation of the series is given, since this is an aid in comparing the results with similar curves that may be deduced from other data. In a recent paper, the writer presented a series of curves showing the probable variation in yearly run-off covering a wide range of values of the coefficient of variation.† In order to compare the rainfall frequency given by Mr. Grunsky with the writer's run-off frequency curves previously mentioned, the coefficient of variation (*C. V.*) of Mr. Grunsky's series has been computed and found to be 0.35. Also, in plotting data of this kind, it is better to consider the percentage of time represented, rather than the number of years in the series, which will probably vary with each record to be studied. Plotting records on the basis of the percentage of time covered, therefore, is also an aid in reducing all records to a comparable basis.

Mr. Grunsky's curve has been replotted in the manner suggested, and the writer's curves for values of *C. V.* of 0.30 and 0.40 are also shown in Fig. 12. The agreement between these curves is close, the greatest deviation being for values between 100% and 140% of the mean. It is possible that rainfall data can be represented best by a type of skew curve different from that which applies to run-off data of approximately the same coefficient of variation. However, it is unfortunate that more data were not utilized in constructing the rainfall frequency curve, since with the many long records of rainfall available in California, a series containing 500 terms or more could have been easily constructed, which would have indicated more definitely the trend of such a curve.

The accuracy of the long-time means determined from the San Francisco and Sacramento records, moreover, is open to question. These records represent a composite of records taken at different locations and with gauges under varying degrees of exposure. The greatest factor contributing to the error

* Asst. Engr., H. L. Haehl, San Francisco, Calif.

† See Fig. 13, "The Probable Variations in Yearly Run-Off as Determined from a Study of California Streams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 244.

of the mean is that in these cities (and more especially in San Francisco), the gauges have been moved from their original locations near the ground to the tops of high buildings. Without going into the details which have already been given in previous papers,* it has been shown in the case of San Francisco, by comparing the official record with that kept by a private observer, that after the Weather Bureau had been moved to the top of the eleven-story Mills Building, the official record showed materially less catch than the private record, whereas prior to that time the two records had been in close agreement. When this subject was discussed previously, various arguments were advanced, defending the official record, but, at the present time, even the Weather Bureau officials recognize that the observations taken at the tops of high buildings do not reflect accurately the conditions near the ground; and it is now the policy of this Department to move its city stations, as fast as funds are available, to some open space where the instruments can be placed at or near the ground.

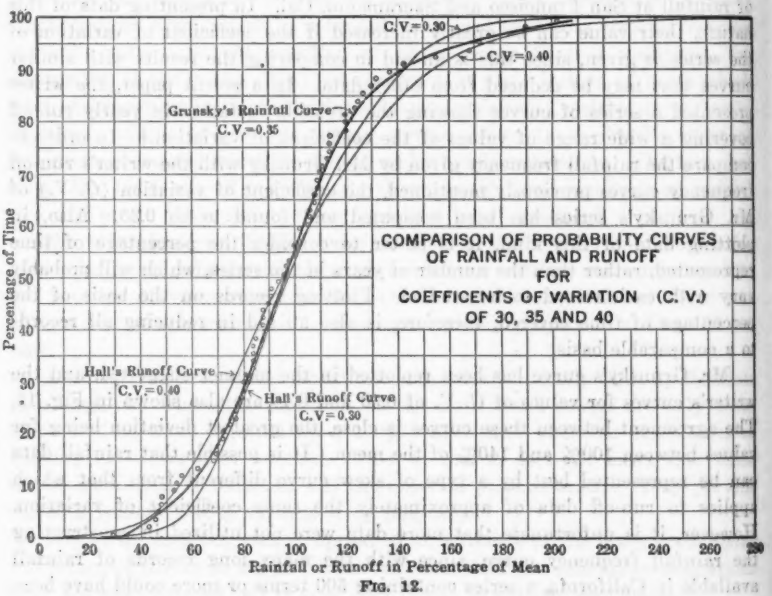

FIG. 12.

While on the subject of the effect of the exposure of rain gauges on the catch registered, attention may be called to an investigation by Messrs. William G. Reed and Howard M. Loy.† This study was originally undertaken for the purpose of making an intensive investigation of the relation

* *Transactions*, Am. Soc. C. E., Vol. LXI (1908), pp. 526-529; and Vol. LXXXI (1917), p. 183.

† "The Water Resources of Strawberry Creek, Berkeley, Cal.", *Monthly Weather Review*, Vol. 43, pp. 35–39; and "Note of Effects of Raingauge Exposure", *Monthly Weather Review*, Vol. 43, pp. 318–322.

between rainfall and run-off on a small drainage area. Strawberry Creek, a small intermittent stream which has a drainage area of about 600 acres, and which flows through the campus of the University of California at Berkeley, Cal., was selected for this purpose. The work was begun in 1913 when five gauges in addition to two permanent gauges on the campus were placed in different parts of the drainage area and read regularly. At the same time the flow of the creek was measured by a weir. The results obtained from the five rain gauges were so unsatisfactory that, in 1914, thirteen gauges were placed on the drainage area, in addition to the two on the campus. In Table 15 is shown the rainfall recorded in the various gauges between May 1st, 1914, and April 30th, 1915, together with the elevation of each gauge and the ratio of the catch of each gauge to the average. The term, expanded total rainfall, which is used, refers to the total recorded rainfall plus certain corrections to fill in gaps in the records at some of the gauges. The variation in the ratio of the catch of the various gauges for individual storms was often much greater than the average given in Table 15, and the records show that the lowest catches are in the gauges most exposed to the wind. It was stated as doubtful whether there was a single good rain-gauge exposure in the area under consideration, and it was believed that all the gauges registered less than the true rainfall. As a conclusion to this study, which was abandoned shortly afterward, Mr. Reed states:

"From a strictly meteorological point of view the most important result so far seems to be the difficulty if not the impossibility of determining the precipitation on a water-shed by means of ordinary rain gauges."

TABLE 15.—RAINFALL OF STRAWBERRY CANYON FROM MAY 1ST, 1914, TO APRIL 30TH, 1915, WITH RATIOS OF INDIVIDUAL GAUGES TO THE AVERAGE.

8.	1 180	28.26	1.05
9.	915	29.06	1.08
10.	1 210	29.06	1.08
11.	1 315	32.03	1.19
12.	1 655	29.06	1.08

It would appear, therefore, that great doubt exists as to the accuracy of long-time means based on composite records. Hence, it would seem that there is nothing to be gained by expanding rainfall records to agree with the long-time means at San Francisco and Sacramento.

It may be of interest to discuss in some detail the results of a study of the relation between rainfall and run-off on Putah Creek, as this stream shows some of the typical difficulties encountered in studies of this nature.

The records of the gaugings of the flow of Putah Creek at Winters, Cal., are available for a period of fifteen years from 1905-06 to 1919-20. The record for a period of nine years has been presented by the writer.* The run-off of the remaining six years need not be shown, except to state that, in 1919-20, the run-off was slightly less than in 1911-12, and that the mean run-off for the fifteen years is 420 000 acre-ft. In order to expand this record over the period covered by the rainfall records, the precipitation by seasonal years for eighteen stations in the neighborhood of the drainage area was collected. After gathering these data, it was found that only seven stations out of the eighteen had complete records for the fifteen years that run-off records were available. Gaps in the records were filled by estimating the missing years from the rainfall at neighboring stations.

Table 16 gives the names of the various rainfall stations, together with the elevation and the mean annual rainfall for the 15-year period. Only one of the eighteen stations, that at Helen Mine on the north side of Mount St. Helena, is within the catchment area, and at this station the mean rainfall is 82.3 in., or more than twice the mean rainfall at any of the other stations. Helen Mine is the only station on a mountain slope, all the other stations being in the bottoms of valleys. Without this station an erroneous idea of the true mean rainfall in the Putah Creek basin would have resulted. From the scarcity and wide distribution of the rainfall stations, it is almost impossible to estimate the mean annual rainfall on this drainage area with any degree of accuracy, although it is probable that it is between 30 and 40 in. In cases of this kind, better results can be obtained by disregarding the actual rainfall and determining the relation between the percentage of rainfall and the run-off.

TABLE 16.

In Fig. 13 is shown the relation between mean annual rainfall and mean annual run-off for Putah Creek, based on the 15-year period covered by the gaugings. The relation between the annual rainfall and run-off has not been shown in the diagram, because the only use that is made of the rainfall run-off relation in this discussion is to determine the relation between the observed and the probable run-off for the period covered by the rainfall records. By using the data in the manner illustrated in Fig. 13, it has been found that

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), Stream 11, Table 1, p. 194.

in practically all cases the relation between the percentage of mean annual rainfall and the run-off can be represented by a straight line.

The percentage of rainfall for each year of the records at each station was calculated on the basis of the 15-year means, and these percentages were then averaged to obtain the average percentage of rainfall for each year. For the 48 years, 1872-73 to 1919-20, there were always at least three stations available for computing the average, but for the 23 years, from 1849-50 to 1871-72, only the record at Sacramento was available. Using the records in this manner, it appeared that for the 48-year period the rainfall was 103.5% of that in the 15-year period, and that for the 71 years it was 109.0% of that in the 15-year period.

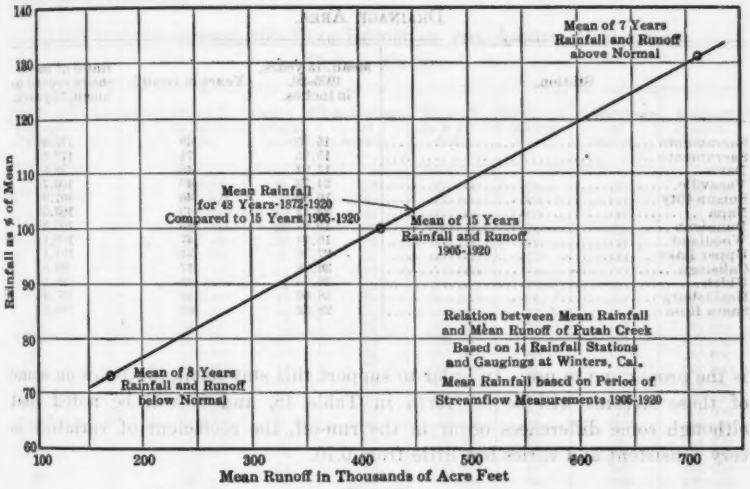

FIG. 13.

From a closer study of the records, it would appear that the conditions which have affected the catch registered by the San Francisco gauge in recent years, that is, moving the gauge to the top of a high building, have affected the Sacramento record in a similar manner. In support of this statement, Table 17 is offered, showing the ratio between the mean rainfall for the fifteen years, 1905-06 to 1919-20, and the mean for the entire record at each station where the records were of sufficient length to warrant making the comparison. The record for Sacramento is shown for two periods, 48 years and 71 years.

It will be noted from Table 17, that the ratio of the rainfall for the entire record to that of the last fifteen years is disproportionately greater in the case of Sacramento than in that of any other station, if either the 48-year or the 71-year period is considered. In view of these results, it would appear that nothing but erroneous results could be obtained by expanding short records to agree with the long-time means at San Francisco and Sacramento.

It was decided, therefore, in the case of the Putah Creek study, that the results obtained from the 48-year period were much more dependable than those for the 71-year period. Using the result for this period and Fig. 13, it would appear that the mean annual run-off for the 48 years should be 450 000 acre-ft. rather than the 420 000 acre-ft., as determined from the measured flow.

In Table 4, Mr. Grunsky has presented the probable range in rainfall and run-off to be expected, in a period of 100 years, from a water-shed in the vicinity of San Francisco having a mean annual rainfall of 30 in. Similar results may be obtained for the run-off—which is really the result finally desired—by using the writer's frequency curves for run-off.* For streams in the vicinity of San Francisco, the curve for the coefficient of variation of 0.70

TABLE 17.—SUMMARY OF RAINFALL RECORDS NEAR PUTAH CREEK DRAINAGE AREA.

Station.	Mean, 15 years, 1905–20, in inches.	Years in record.	Ratio of mean entire record to mean, 15 years.
Sacramento	15.95	48	115.9
Sacramento	15.95	71	117.6
Davis	17.24	48	98.8
Vacaville	24.73	40	106.7
Suisun City	19.80	46	101.9
Napa	23.12	43	103.5
Dunnigan	19.07	43	103.5
Woodland	16.24	47	108.1
Upper Lake	27.16	34	101.1
Calistoga	36.98	47	99.3
Ukiah	36.75	43	99.5
Healdsburg	38.66	43	107.4
Santa Rosa	28.42	32	106.3

is the proper one to use. In order to support this statement, statistics on some of these streams will be set forth in Table 18, and it will be noted that although some differences occur in the run-off, the coefficient of variation is very consistent and varies but little from 0.70.

TABLE 18.—SUMMARY OF RUN-OFF RECORDS IN THE VICINITY OF SAN FRANCISCO, CAL.

Stream.	Place.	Years in record.	Area, in square miles.	Mean run-off, in inches.	C. V.
San Leandro	Oakland	34	42	9.0	0.73
Crystal Springs	San Mateo	30	36	11.1	0.69
Alameda	Sunol	29	690	4.8	0.74
Coyote	Madrone	18	193	7.5	0.80
Putah	Winters	14	805	10.5	0.67
Cache	Yolo	16	1320	7.8	0.74

Applying this method to Putah Creek, Table 19 shows an ideal 100-year record of annual run-offs for this stream, arranged in order of magnitude, and based on a mean annual run-off of 450 000 acre-ft., and a coefficient of variation of 0.70.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 244.

The percentages given in Table 19 will apply equally well to any stream having a coefficient of variation of 0.70, and the yearly run-off can be obtained by multiplying these percentages by the mean annual flow. The method of obtaining these percentages has been explained in the writer's paper previously mentioned.* The minimum run-off to be expected once in 100 years on Putah Creek at Winters, or 13 000 acre-ft., is equivalent to a depth of 0.30 in. on the drainage area, while the maximum run-off, or 1 521 000 acre-ft., is equivalent to a depth of 35.5 in. on the drainage area. The figures given in Table 19 may be used in constructing an artificial record of any desired length, which will be comparable to an actual record of similar length obtained under natural conditions.* Such a record is interesting and instructive, as from it the probable frequency of the re-occurrence of any series of dry years can be foretold with reasonable accuracy.

Some space has been devoted to a discussion of the desirability of having the Weather Bureau publish rainfall totals by climatic or seasonal years rather than by calendar years. Although the annual summaries published by the Weather Bureau give the precipitation by calendar years only, bulletins of climatological data are issued at intervals of a few years, in which the entire

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), pp. 250–251.

record of rainfall at each station to the date of publication is given both by seasonal and by calendar years. In order to bring the records to date, it is generally only necessary to secure the seasonal totals over a short period of years.

H. V. HINCKLEY,* M. AM. SOC. C. E. (by letter).—The Engineering Profession is certainly indebted to the author for making public the results of his investigations. The writer would not attempt to estimate the loss of capital invested in hydraulic works, during the past thirty or forty years, from lack of such information.

Time was when, in the absence of more complete information, the evaporation tests which had been made by water supply engineers along the Eastern seaboard—and which were widely published—were accepted as probably applicable over the United States in general. This mistake, coupled with a lack of appreciation of the distinctive differences between rainfall and run-off in different sections of the country, has been partly responsible for great losses.

The conditions prevailing in New England and the seaboard States, are quite dissimilar from those which prevail on the Great Plains. Even the casual observer who travels, knows that in the Eastern States the streams flow the year around, while, in parts of the West, the streams are dry fifty-one weeks of the year and, human-like, make up for lost time by getting soaked and going beyond customary limits during a part of the remaining week.

The writer has previously referred† to the comparative fluctuations of the Connecticut and Kansas Rivers. On the Great Plains, extremes prevail. Drainage areas, reservoir capacities, and spillway capacities must be maximum, while at times results as to water supply will be minimum. For example, since 1900 there have been two years when the run-off in parts of Oklahoma, for sixteen months (including four months of the contiguous years, in each case), has been less than 4 in., while the evaporation for the same period has been about 10 ft. The writer discovered, in the early Nineties, that an average annual evaporation of 3 ft., or a maximum evaporation of 6 in. per month, did not apply to the case of hot winds on the Plains where evaporation was as high as 2 in. per day, for 15 or 20 days at a time.

The author's formula for annual run-off, in which P is less than 50 in., has always checked the writer's computations (based on actual measurements at neighboring points similarly situated), to within a small fraction of 1%, and those cases include the two extremely dry years previously mentioned. The writer, therefore, considers Mr. Grunsky's simple and easily remembered run-off formula one of the best tools in his engineering collection, and believes that it entitles the author to at least a passing compliment.

WALTER E. JESSUP,‡ ASSOC. M. AM. SOC. C. E. (by letter).—The author has collected and evolved formulas expressing relations between rainfall and run-off, which can be made to be very useful. It is desired, however, in connection with the examples presented by Mr. Grunsky of applications of

* With V. V. Long & Co., Oklahoma, Okla.

† *Transactions*, Am. Soc. C. E., Vol. LVIII (1907), p. 34.

‡ Asst. Engr., Quinton, Code and Hill, Los Angeles, Calif.

his Equation (25), namely, $D_m = 413\ a\ M\ I$ sec-ft., giving maximum stream flow from the intensity of a rainfall on a large drainage area, to point out that this formula has its limitations.

The author has given, as examples, the drainage areas of the American River above Folsom and of the Sacramento River above Red Bluff. As stated, the greater part of the yearly precipitation on the Pacific Slope occurs during the winter months. The average elevation of the 1 900 sq. miles of the water-shed of the American River, is nearly 5 000 ft. above sea level. Therefore, a large part of the precipitation will fall as snow and will not run off at once. The average elevation of the 9 300 sq. miles of the water-shed of the Sacramento River is about 4 000 ft. above sea level, and a large part of the precipitation takes the form of snow for similar reasons. The floods on both these rivers occur for the most part in the spring of the year as a result of melting snows.

Assuming that the maximum rainfall of 8 in. in 24 hours should fall in the form of rain, on the water-shed of the American River in the spring, there will be added to the run-off from such a rain, the tremendous run-off from the melting of the accumulated winter snows, the result being a value far beyond the expectation of the formula. On the other hand, should this same precipitation occur during the winter, it will be retained largely on the water-shed in the form of snow, and only a small proportion of the run-off, as computed from the formula, will result. Such unreasonable results will also obtain from a maximum rainfall of 6 in. in 2 days on the water-shed of the Sacramento River.

It would seem, therefore, that the application of the formula has been carried beyond a reasonable limit, and that it will not apply to such large water-sheds where the conditions affecting precipitation are so variable.

E. W. Clarke,* M. Am. Soc. C. E. (by letter).—The writer is interested in Mr. Grunsky's suggested method of expanding short-period rainfall records, and although it is understood that special reference is made to California conditions, it may be worth while to compare the theoretical results obtained by the expansion with the rainfall at some long-term stations in New England, using still longer records at other stations as a base. It is evident that this method of expanding rainfall records may also be applied to run-off records.

X. H. Goodnough, M. Am. Soc. C. E., Chief Engineer of the Massachusetts State Board of Health, has collected a large number of rainfall records in New England,† some of which are as follows:

New Bedford, Mass.	1814–1920
Boston, Mass.	1818–1920
Providence, R. I.	1832–1920
Lowell, Mass.	1826–1920
Amherst, Mass.	1836–1920
Waltham, Mass.	1825–1920
Springfield, Mass.	1846–1920
Concord, N. H.	1853–1920

* Dist. Plant Engr., U. S. Shipping Board, Baltimore, Md.

† *Journal*, New England Water Works Assoc., September, 1915, and September, 1921.

Using as the base time, the 50 years, 1871 to 1920, inclusive, and as the base stations, New Bedford and Boston, the rainfall was calculated to the limit of each of the other stations from one or the other of the base stations and sometimes from both; also, in a few cases, by using one of the sub-stations as a base, and the results of these calculations and the actual recorded rainfall were plotted.

The plotting of the annual rainfall showed that, in general, a wet or dry year at the base was also a wet or dry year at the sub-station, but the theoretical and actual quantities are often far from agreement. In cases where the theoretical rainfall was calculated from both bases, there is also generally a lack of agreement between these figures.

The mass curves showed that there may be practical agreement for a number of years, but this agreement never follows throughout the entire period and it happens, in most cases, that the difference is on the wrong side, that is, less rain fell than the calculations indicated as probable.

The maximum distance between stations is about 95 miles. At the various stations, rainfall conditions differ, but the writer does not consider them so dissimilar as to make it unfair to the theory to include them in the test. If the application of the theory is confined to much smaller areas than this, its value is nullified. So far as these few cases indicate, distance within these limits does not seem to be a factor, since the variation between the theoretical and actual at Amherst, calculated from Boston 75 miles away, is no greater than at Waltham, 12 miles distant from Boston.

This test of the theory apparently indicates that, as far as New England records are concerned, reliance cannot be placed on this method of expanding short-term records to give even approximate estimates of the precipitation for the years not covered by the record. In view of the general discordance of the theoretical and actual rainfall lines, not much reliance can be placed on the calculated maxima and minima; on the contrary, at one station the maximum and at four stations the minimum estimated, was exceeded by the actual rainfall.

W. W. Horner,* M. Am. Soc. C. E. (by letter).—The writer feels that Mr. Grunsky's paper, as supplementing his earlier paper on the same subject,† is of the greatest interest to the Engineering Profession, particularly in keeping before engineers the lack of information available on certain phases of this subject. With the adoption of the rational method of determining run-off, a great step was made in advance in this particular science. For its satisfactory application there are two fields in which study is still required, the first relating to intensities and duration of rain, and the second to the rates of run-off.

With the increasing number of automatic rainfall gauges installed, knowledge of the variations of rainfall intensities, with respect to the duration of the rain, is rapidly approaching a satisfactory condition. The writer has made a study of a number of records for various localities, and although Mr. Grunsky's parabolic formula of variation does not appear to conform closely

* Chf. Engr., Sewers and Paving, St. Louis, Mo.

† "Rain and Run-Off near San Francisco, California", *Transactions*, Am. Soc. C. E., Vol. LXI (1908), p. 496.

to general data, the writer believes that its use will be valuable in a preliminary way in districts where detailed studies are not available. He agrees with the author that it should never be used where sufficient observed data are available to permit of a satisfactory rainfall curve for the particular locality, or where such curves are available in the same general district and under the same meteorological conditions.

Another phase of the rainfall studies on which little information is available is the intensity and area of relationship, that is, a determination of the area over which single-station maximum records are applicable, or the extent to which they should be reduced in applying them to large areas. In a number of cities, a sufficient number of automatic rainfall gauges are now located to permit of a study of this kind. It is being undertaken in St. Louis, Mo., in the analysis of ten-year records from five gauges, and it is hoped that, in another year, something of value may be available from this source.

In the matter of percentages of run-off, or of rates of run-off for particular intensities, the writer feels that little progress has been made. Engineers are still dealing almost entirely with arbitrary values, or, in a few instances, with values based on personal experiences. Published gaugings on existing sewer districts are few, and many of the records are faulty. Even where the records are unquestionable, the results for different storms vary so widely that engineers have not yet been able to make them conform to a definite theory. The writer has no doubt that as such records multiply, accompanied with all the information which may be of interest as affecting run-off, some definite values will be developed.

The studies of the first three years of gaugings in St. Louis were rather discouraging, and the matter was laid aside for the accumulation of further data. With records for ten years now available, it is again hoped that some law of variation in run-off will become discernible. These gaugings, like most of those heretofore recorded, deal with the run-off of mixed urban areas of from 20 to 500 acres in extent. The writer has long felt that the analysis of these records would be much simplified by a study of the run-off of small plots of uniform character. In an effort to secure such data, the run-off from single blocks is being studied in St. Louis, and it is also proposed, in the near future, to make a study of the run-off on large roofs. To complete this series, observations will be made of the run-off from small plots of natural soil.

The writer has been interested in the results of the study of this character made by the Miami Conservancy District and published in Part 8 of its Technical Reports. These results give definite information of the effect of varying intensities of rainfall on run-off from natural soils in the vicinity of Dayton, Ohio. It is surprising to note the capacity of these soils for continued absorption of surface water and for passing this water through to the underlying gravels. The measurements show clearly that, for the shallow topsoils and glacial gravels of this part of the United States, the percentage of run-off will decrease with the decrease in intensity, or, in general, with the duration of the storm. It should be evident, however, that this variation is

not applicable outside these particular soil conditions, and it is to be expected that, with the surface loams and plastic clays found generally south of the Ohio and Missouri Rivers, saturation may be expected in a comparatively short time, and that, in most instances, the percentage of run-off will increase with the duration of the rain.

The writer feels that this latter relation will also apply to most urban areas, and that some variable factor of run-off must be introduced into the application of the rational method, rather than values such as the a suggested by Mr. Grunsky, which are constants for any particular density of population.

There is no doubt that engineers must take account in some way of the reduction of run-off due to water in storage on the surface, and to a minor extent in the conduits. Mr. Grunsky's factor of 0.645 is apparently a secondary run-off coefficient to allow for this effect. Ultimately, the propriety of any constant value for this purpose may be questionable. With the present knowledge of the subject, however, Mr. Grunsky must be commended for his effort to take this into account.

The writer feels that Table 6 is unfortunate, in that it shows values extending far beyond the range which the author claims for his formula. It would seem preferable to have introduced only the lower part of this table, dealing with times of from 1 to 20 days. The writer feels the more strongly on this point because he does not believe that the marked reduction of the values of a with an increase in time are justified for rains of less than 1 day, and seriously questions whether, for these short times, the values of a should not increase somewhat as the time increases.

The writer's experience with the application of the rational method in the design of sewers in St. Louis has led him to the conclusion that the simple and direct use of the method involves less work than the solution of formulas of the type presented by Mr. Grunsky. It would seem unfortunate to have to make preliminary studies of the water-shed for the purpose of determining the time of flow, and of drainage areas which would correspond to fractions of this time, when in the ordinary use of the rational method the solution in each section of the conduit provides all the data of this type required for the succeeding section. It appears that the use of Mr. Grunsky's formula will involve about twice the arithmetical work required by the simple application of the rational method.

C. E. GRUNSKY,* M. AM. SOC. C. E. (by letter).—The statements of Mr. Hinckley with regard to evaporation in parts of Oklahoma, should be taken with some allowance. Even in the hot, dry, almost rainless, and quite windy Salton Basin, California, the mean monthly temperatures of which are higher than those in Oklahoma, the annual evaporation from an open water surface is only about 6 ft. The writer would regard, as highly improbable, the evaporation of 10 ft., from an open water surface of any considerable depth and extent in 16 months, including 4 months of the contiguous years. This is also true of a rate of 2 in. per day for 15 to 20 days at a time. Such

* Cons. Engr., San Francisco, Cal.

rates would obtain only from small experimental apparatus or from soil kept wet almost to the saturation point.

Possibly Mr. Jessup is correct when he assumes that the greatest discharge of such a stream as the American River, California, will occur when a heavy rain falls on snow. The maximum melting effect will be due to a so-called warm rain; but the rain of maximum intensity is usually the cold rain which comes near the end of the storm. It will probably be found to be true that rain water plus water due to melting snow will never exceed the predicted maximum rain intensity for the entire water-shed. The checking of the suggested formula against any known results, where melting snow contributes to the peak discharge, is invited. If maximum rain intensities for the water-shed are properly determined and if topographic features have been properly considered in estimating the critical time, it is believed that the formula will be found to be dependable, even under the condition suggested by Mr. Jessup.

The statement by Mr. Clarke that the method of expanding short-time records to long-time records is applicable in the case of run-off as well as of rainfall, is true, but the data relating to measured run-off are accumulating slowly and in many parts of the United States the relative quantity of annual water production can only be determined for the long-time period from the rainfall records, which are generally available. He is correct when he states that the computed quantities of rain for any sub-station will frequently depart materially from the measured quantity. This cannot be otherwise; but it does not detract from the value of the computed quantity (when no measured quantity is available) as an element for predicting what may be expected in the future. Furthermore, as stated by the writer, there is less chance of agreement between any computed rainfall and the measured rainfall for a station, in regions such as the Atlantic Coast and the Middle West where thunder-storms, usually of small extent, occur. This, however, does not destroy the serviceability of the method as a basis for predictions of what may happen in the future. It must always be borne in mind that the purpose of studying rainfall and run-off of past years is to lay a foundation for the prediction of future probabilities. It can matter little, therefore, if predictions for individual seasons depart considerably from measurements. It is the possible sequence of seasons of various quantities of rain and run-off that is of consequence.

The writer is in accord with Mr. Wood as to the value of the study of flow records where they are available for a sufficiently long series of years. They are particularly valuable for the streams in the Eastern United States, the range of discharge of which is much less than that of streams of the Pacific Coast. However, it will hardly do, as he suggests, to use the run-off records of streams from other regions as a basis for expanding a short-time Pacific Slope record. The first requisite, in such comparisons, must always be similarity of climatic and general topographic and geologic conditions.

The reasons given by Mr. Wood for adhering to the calendar year, in the matter of rainfall and run-off records, have little to commend them. The calendar year is good enough perhaps for the Southern Hemisphere where

the New Year comes in a low-water period. It was a mistake to have adopted it for the Northern Hemisphere, and the mistake should not be perpetuated. The improved practice, for the reasons stated by the writer, should be adopted, but the division of the year that is intended and that should be adopted, should be the same for all parts of the United States.

The writer is particularly gratified to note that the U. S. Weather Bureau is giving careful consideration to the matter of revising the method of tabulating observations, as shown by the comments of Dr. Marvin, Chief of the Bureau, and some assurance has been given by the Bureau that in California the regular publications, if not modified, will at least be supplemented with a special publication of the rainfall data in more useful form.

The discussions of Messrs. Hering and Landreth are of interest, but the writer does not wish to be understood as claiming that evaporation is the only factor that causes less water to run off than has fallen, as rain or snow, on any area. What is claimed is that evaporation is the predominating factor and that transpiration, the assimilation of water by growing plants, and evaporation, may be grouped together and for convenience called "evaporation". The causes making for reduced evaporation at high altitudes cited by Professor Landreth are offset in some measure by the fact that, at the high altitudes, snow remains long on the ground and there may be consequent replenishment of soil moisture long after the rain has ceased. It is not believed that any attempt to introduce other factors than temperature, which is the main index of the rate of evaporation, into the equation will meet with success and if the coefficient appearing in Equations (13) and (14) has been determined for one or more water-sheds of any region, these equations should be found useful as written.

Mr. Horner's suggestion that the value of the permeability factor, a, should not be constant for any density of population, will readily be conceded. The factor to use and how to vary it, must be left to the judgment of the engineer and the degree of approximation that is desired. The variability of this factor is recognized by the writer, as shown in Equation (29), and the resulting Table 6. Mr. Horner suggests, too, that Table 6 has been extended too far. Experience alone will determine this on the basis of comparison of measured maximum discharge with the estimated discharge, when the facts relating to rainfall on the water-shed are sufficiently well known to make a comparison.

As an addition to the paper, it should be noted that, in using Equation (13) for run-off estimates, the mean temperature of no month should be entered at less than 32° in the calculation of the value of f. It should also have been stated that the coefficient, C, in Equation (14), is probably inversely proportional to n, the number of months, and that, consequently, Equation (13) is applicable regardless of whether the rain that produces the run-off, falls in 6 or 7 months, as on the Pacific Coast, or is more uniformly distributed to all the calendar months, as in other parts of the United States.

NATIONAL PORT PROBLEMS*

A SYMPOSIUM

BY MESSRS. FREDERICK W. COWIE, LANSING H. BEACH, FREDERIC H. FAY, M. A. LONG, J. ROWLAND BIBBINS, JOHN MEIGS, W. WATTERS PAGON, EDWIN J. CLAPP, CARROLL R. THOMPSON, JOHN A. BENSEL, WILLIAM J. WILGUS, B. F. CRESSON, JR., AND H. MCL. HARDING.

WITH DISCUSSION BY MESSRS. WILLIAM H. ADAMS, ARTHUR M. SHAW, T. F KELLER, HARWOOD FROST, L. F. BELLINGER, JOHN H. MCCALLUM, FRANK W. HODGDON, M. G. BARNES, NELSON P. LEWIS, AND T. HOWARD BARNES.

* Presented at the meetings of September 7th and 8th, 1921.

NATIONAL PHASES OF PORT PROBLEMS

By Frederick W. Cowie,* M. Am. Soc. C. E.

What is a National port? National ports stand for policy, also projects.

In recent years, increasing productiveness, the tremendous increase in foreign commerce, and the increase in population, wealth, and industrial activity, has not been followed, or even equalled, by the commensurate, scientific development of ports.

The transportation problem of a nation is one of the fundamentally vital economic questions of the day. It is not one of limitations as regards the individual or the locality. It gives additional prices to the farmer for his produce; it enables the manufacturer to compete with his foreign rivals; it cheapens the necessities of life; and it gives employment to labor and capital alike. A successful National port, therefore, is widespread in its effect for good. It may and frequently does constitute the deciding factor as regards a competitively successful National route.

A National port is an important link in the transportation system of a nation. A successful National port is a distinct aid in the solution of the transportation problems of a country.

A National port must bear a clear relation to a logical, economical, and widespread necessity. To be truly National, a port, or series of ports, must be required by the nation and directly or indirectly it must yield comprehensive advantages. In consequence, few port locations fulfill the necessary requirements. A port, however, may be National in part for comprehensive collective and distributing functions, and local in part to fulfill city or State requirements.

Although a National port is of general value to the nation, it is obviously of particular value to the city in which it is located and to the hinterland which it serves. The district through which the transportation route runs collects transportation tolls all along the line. To distribute the benefits and to divide the burdens alike has ever been the difficulty.

A State, a city, or even a corporation, may decide, in view of expected financial and commercial results, to develop an advantageous natural harbor, even though no great comprehensive or National economic interests would be served. In no sense could this be considered a National port. On the other hand, it would be logical to infer that a comprehensive unit of a port may be developed to meet National requirements and that, in the same harbor, other units may be developed to meet local or more city requirements. A combination port developed and administered, alike for National and for restricted requirements, both as to benefits and the assumption of financial burdens, would give ideal results. The one may not be successful without the other. The combination results in excellent working conditions.

An island nation having only short distances to the seacoast may be better served by a number of local ports. Transportation is not a problem in this case. No comprehensive general interests would be served by the development of one or more particular ports. All producers and consumers have the

* Chf. Engr., Harbor Commrs. of Montreal, Montreal, Que., Canada.

competitive advantages of short transportation distances and cheap freights. On the contrary, a country having an extensive hinterland and a short seacoast and having rival foreign competitive transportation routes, essentially requires a system of National ports. The transportation problem in this case is to find the best National route, develop it, cheapen it, and use it. Transportation tolls are kept in the country and constitute a National advantage, even though the foreign route may be cheaper to some extent. Many rich hinterland areas cannot be developed successfully or opened up for settlement and production, without National aid toward cheap transportation. In particular, therefore, a country having immense transportation distances and productive hinterland areas, vitally requires a National transportation policy, with more or less clearly defined National routes, wisely developed National ports, scientifically improved, equipped, and operated in the interests of a nation. Such examples as the United States, Canada, Brazil, Russia, and Germany may well be cited.

In the United States the genius of commerce is one of the important characteristics of the times. It is a function of the nation rather than of the individual. National prosperity is vitally dependent on commerce. Transportation is one of the important phases of commerce. A transportation policy is essential. This policy, as to its National well-being, may be compared with its fiscal or banking policy. Production may be hampered; manufacturers may not be able to compete; the necessities of life may cost too much, if a satisfactory solution of the transportation problem is not achieved.

The so-called "pork barrel policy" is directly and indirectly the antithesis of the National port policy. If certain ports, natural or artificial, can, by scientific development, be made by the nation of value to the people in general, such development will be in line with a National port policy. It does not follow, however, that because of National expenditure on these certain ports, similar or proportionate National expenditure must be made on others which are not so essential in connection with the adopted National routes.

National ports must be connected with trunk lines, not with local lines or feeders. Is it reasonable to expect that a nation can be asked to sanction such a National port policy which, though general in its good results, must be more generous to some ports than to others? History demonstrates an affirmative reply. A necessary project for the country will command universal approval, even at some sacrifice of the few. Admiral William S. Benson, U. S. N., is recorded as saying, after seeing other harbors and ports of the world: "We [the United States] have not really a first-class harbor, *viz.*, scientifically constructed and developed."

The speaker has seen and studied most of the great harbors of the world and, in his opinion, no country, other than the United States, except possibly Canada, has greater necessity for scientifically developed harbors and. in no country of the world, can be found more favorable opportunities. Transportation is fundamentally essential; distances are great; and routes are well defined. A single great city in the United States possesses two of the most magnificent railway passenger terminals in the world. They are so splendid, so successful, so representative of the spirit of the people, that it is

incomprehensible that there is not one or more similarly representative ocean terminals. It may not be a nation's business to build something splendid for one city, or one State, or one steamship line, or one railway system, but a splendid ocean terminal in the greatest port in the world, at the gateway to three-quarters of the passenger commerce of the country, is a sane vision. Moreover, if properly co-ordinated, with a comprehensive National port unit, it would be an extraordinarily attractive and paying proposition.

Canada, with her great central but rich productive areas, her necessarily long east-and-west transportation, and her limited financial resources, is making wonderfully successful progress. There are notable examples of National ports in Canada. There are others partly National and partly local and they are making wonderful strides in helping to solve that most critical Canadian effort, *viz.*, the development of her vast areas in order to enable her people to compete in production and industry with other nations of the world.

Brazil is in the process of development and is successfully exploiting the nebulæ of what in time will become an organization which will result in the successful development of a great country.

The case of Russia is at present desperate. When the regeneration comes, if that vast country is to be successfully developed, a series of National ports on the east, south, and west will be one of her first necessities.

The Port of Hamburg, with its auxiliary, Cuxhaven, is reported to have cost the State of Hamburg little short of $100 000 000, and that the dues collected did not nearly pay the expenses of the port system. It was, however, a National port, and the deficit was cheerfully met from other sources of revenue. A similar courageous and wise policy of port development in America would surely result in widespread and remunerative trade and commerce, both in the United States and in Canada. There is no example in ancient or modern times of such a proportionate trade and commerce as was developed in Germany from 1888 to 1914. A settled purpose made itself manifest; a National transportation policy was adopted; routes were developed and encouraged for the purpose of increasing trade and for conducting it within the limits of the Empire. National privileges were granted to certain ports making them National ports, and the Empire prospered.

A National port, therefore, may be defined as one of the most important factors in the solution of the National transportation problem. This problem does not exist in certain countries. It is of vital economic importance for the prosperity and development of other countries having large productive areas and long transportation distances. What question would require more serious study, greater skill, or be more in the general public interest? The engineer has great responsibilities; he should be well posted when called on for advice.

Accommodation and Facilities Required by a National Port.—In order to measure justly what facilities may be required to take care of National port business, the characteristics of that business may be enumerated:

1. Ocean passenger business.
2. Mails and express.
3. Exports.
4. Imports.

5. The storage and handling of grain.
6. The storage and handling of perishable products.
7. General warehousing.
8. Adjuncts necessary for an ocean port.
9. Facilities and accommodation for collecting, receiving, assembling, re-manufacturing, conditioning, and distributing both from and to all ports of the world and from all points in the country.

Reduced to a single picture, the requirements for a National port may be visualized as follows: One or more comprehensive units capable of taking care of all the varied port business, co-ordinated and concentrated in a central location on one of the main natural routes, where the ship and the railway meet and where commerce may be collected, stored, and handled with economy and dispatch. It would appear, therefore, if this argument is accepted, that much of the port development of the present day is being carried out on lines absolutely contrary to the best requirements of a National transportation policy. Take location: Are the best, most centrally located sites for port development being secured no matter what the cost? Are comprehensive units being designed, so that everything required in connection with the prompt and economical loading and unloading of ships may result? Is concentration being adopted as a necessary principle? What about co-ordination? Who is responsible for the railroads designing ocean terminals?

In North America the super-skill of the designers of everything pertaining to railroads, bridges, the development and use of electricity, the motor industry, bulk-cargo handling, sky-scraper buildings, and tunnels is an acknowledged fact. Is this super-skill in evidence in the ports?

New York City which possesses the greatest port in the world and where the lead is taken in almost every phase of originality and skill in design, is, in the opinion of many, setting a very bad example in the development of her port from the standpoint of the inland producer and consumer. The local trade of the great city is such a valuable freight and such a high proportion of the port business, that ships and shipping declare for New York, in spite of the records of economy and dispatch. Competition has not been a factor and has resulted in indifference. Necessity did not require to mother invention.

The port problem in New York, as compared with other successful National ports, such as Hamburg and even Montreal, also appears to be so simple. What is the area of the Port of New York? How many miles of water-front has it? It is reported that in the combined Port of New York and New Jersey, the harbor shore line is about 700 miles in length. The developed water-front is 380 miles long.

The Port of Hamburg covers an area, 4 miles long by 2 miles wide. The harbor of Montreal has a shore-line water-front of 34 miles, while the developed water-front is only about 12 miles in length. In Montreal, centralization is one of the essential features of success. The value of port locations or berths may be judged from wharfage revenues on goods. A pier, dock, or transit shed, and dredging, costs no more in a central location than in an outlying district. The land or shore areas required are tremendously more

costly, but modern facilities may be designed for such sites, which, by concentrating effort, may multiply usage, with good financial results.

In the twenty fully equipped berths in the harbor of Montreal, centrally located along a mile of shore front, more than 75% of the business of the harbor is carried on. The revenue from wharfages on goods alone amounts to between $40 and $50 per lin. ft. of dock front per annum, including ends, bulkheads, etc. A mile distant, where railway and city approaches are not so favorable, but where docks, dredging, wharf spaces, roadways, etc., cost just as much, the wharfages amount only to approximately $10 per lin. ft. per annum. Three miles distant, with excellent railway and city approaches, with distance as the only drawback, the revenue return is about $12 per lin. ft. per annum.

To "centralize" a summing up: The Port of Montreal records a commerce in seven months, of between one-fifth and one-sixth of the commerce of the Port of New York in twelve months, and this without congestion and with a water-front development of one-thirtieth of that of New York. In New York, as in several of the other ports doing National business, there is ample opportunity, there is necessity of centralization, concentration, and comprehensive facilities for economy and dispatch for the Nation's business.

Whose Function is the Development, Construction, and Operation of a National Port?—Assuming that a nation adopts a National transportation policy, including the system of National ports, it is logical that the nation, through its representatives, has the deciding voice in all matters pertaining to policy, finance, and control. There are various principles which may be adopted in the carrying out of this policy. The matter may be placed in the hands of a Government department; it may be placed in the hands of the engineers of the Army; or it may be taken care of by direct legislation.

In order that the policy may be absolutely impartial and in the interests only of the country in general, the consideration of this transportation policy should be placed first, last, and all the time, in the hands of men who have no special interests to serve, and who have no political aspirations. Experiences during the World War are fresh in the memory. Organization after organization under the stress of vital requirements was made subservient to new methods, dependent on direction by men who had been unusually successful in some line of business or commercial activity. This resulted in an unexampled success. Problems previously considered open for individual effort, for gain, were relegated to National conferences of mind and effort. The "dollar-a-year men" were available for the critical requirements of the war. They are ever available for honorable positions at the country's call. Theirs would be the hands into which the transportation problem could safely be confided.

Although men who have already made their mark commercially or financially may be found, who will assume an honorable position and "carry on" for the honor of their country, there is another equally important phase in the success of a National port system. Port administration and port engineering are tremendous factors affecting the success or failure of such plans as would enter into the complete National system. It is probable that in no other

branch of engineering can so many costly mistakes be found. It is probable that in no other branch of engineering have the principles of success and failure in the past been so overlooked. It is a fact that no engineering study, technical or practical, can be found so absorbing, so interesting, and so valuable, when properly developed principles are carefully adhered to. In Europe, where competition in ports is so keen and where ports in general are carried on as public obligations, port engineering ranks among the very highest in the Profession.

Furthermore, the questions of continuity and permanence in connection with the conception and scope of port projects cannot be successfully answered by a system where administrators, engineers, and other technical and practical officers are changed at frequent intervals. The European system by which the best men are obtained, and permanently retained, by which, competitively, they are called on to make good and when successful are free to act independently and according to their best judgment, would appear to be a necessary principle in National port organization.

It would appear, therefore, that the development, construction, and operation of a National port system should be considered first in connection with a National transportation policy. This policy must necessarily be under the direction of the representatives of the people. Impartial direction must be given as to its magnitude, scope, and carrying out. This organization, to be truly National, should be undertaken as a duty, with public honor as the reward. Great public corporations are so directed by men who have successfully developed the various phases of success in commercial life. Successful men, in developing and building up the country's business, may be found to formulate and recommend for legislative approval a transportation policy and to direct its administration.

As a successful port owes much of its success to an advantageous location, it follows that the authorities of that location, therefore, have a vested voice in its development and operation. The hinterland served by the port has at least an equal voice, as providing the commerce for its revenues and a share in its cost, and because of its interest in economy and dispatch. Subject to the administration of the National Board, the various units of a National port system would have full local control and carry out the National units in co-ordination with the local or city port facilities.

From the point of view of the speaker, therefore, after a life-long study of the design and operation of ports, it would appear that a country desiring the adoption of a National port system, should place the development of the policy in the hands of successful men, who for the honor of their country are willing to serve, and their policy and recommendations should be authorized according to an approved programme.

Each National port scheme, adopted by the National commission, should be placed under a local commission having one representative from the hinterland, one from the line of route, and a chairman from the port city. This local commission, subject to the programme of development, expenditure, and administration, should be free and independent and should be remunerated according to its duties and responsibilities. Cheap money would be avail-

able. As far as possible, each unit should operate at cost, but the nation which would reap the benefits, should be responsible for such interest charges as are not met. It is a recognized principle that in a plan, which is essential to the well-being of the nation, and which cannot be financially developed by a city or a corporation, must be developed, either directly by the nation, or indirectly by some aid which will enable it to stand on its own feet.

Cheaper and more prompt transportation is required by the people in America. If corporations, cities, or the State, do not provide the remedy, it will not be long before the farmers, producers, and industrial interests of the interior take a hand. The coast cities have had their turn. If the country is not satisfied, the National port policy is open for trial.

It might reasonably be suggested that it would be in order to outline that which would constitute a central concentrated, co-ordinated and comprehensive unit, which would be for the well-being of a nation.

In the first place, the location must be impartially chosen, and it must be on a National route. It is most desirable that the unit should be in the very center of a harbor, close to business and trade originations. Approaches from ocean routes, connections with all railway lines, and access from city traffic centers should be perfect, or possible of being made so.

To be self-contained, the unit should comprehend: A bulkhead passenger landing quay, having berths for at least two of the largest ocean vessels on the route, approachable at all stages of the tide, and connected with a railway passenger-and-mail special siding.

The freight accommodation should be sufficient for at least twenty-five first-class berths, all closely co-ordinated. Each berth should have transit sheds, with accommodations and facilities for entering, unloading, loading, and clearing in five days.

Railway accommodation, and vehicular and lighterage facilities should be ample and sufficient for the aforesaid traffic. Warehouses should be provided for all staple products, such as for the collection, storage, and handling of grain, flour, cotton, sugar, tobacco, etc., all connected for mechanical handling to and from the ships, and with railway cars.

Cold-storage facilities should also be provided so as to develop production in the country, and to cheapen the essentials for the population.

The high priced central sites could be made revenue producing by constructing upward, for offices, manufacturing lofts, sales rooms, exhibitions, etc. The whole unit should be of a permanent character and absolutely fireproof, in order to command low insurance rates. The style and types should be worthy of the nation. If this is what a country wants, it will have it.

TERMINALS

By Lansing H. Beach,* M. Am. Soc. C. E.

The speaker will confine his remarks largely to the duties respecting terminals as imposed by law on the War Department and on the Corps of Engineers, and in explaining that attitude toward the port and terminal situation in general.

A seaport terminal may be considered to consist of land approaches, whether by rail or highway, of the terminal structures proper, including the wharf, pier, or quay, the transit shed and the necessary supporting warehouses, and the water approach. Speaking for the moment only of the latter, it is the policy of the United States Government to limit itself to work on the outer or channel side of the main harbor line, leaving to the owner of the terminal in question the making of any needed connection between the main channel and the face of the wharf or quay.

As a rule, the Government creates the main channels, usually in the past without any assistance from the locality concerned, and once these channels have been completed, maintains them, and improves and adds to them from time to time as the demonstrated needs of traffic may demand.

The admirable and comprehensive report of the New York-New Jersey Port and Harbor Development Commission is no doubt familiar to engineers, and its plans and general recommendations are known. Having in mind what is proposed in the way of future developments in the Metropolitan District, it may be interesting to summarize briefly the principal channels already created and maintained by the United States. These include the Ambrose Channel, which is 40 ft. deep and 2 000 ft. wide; the Gedney, or Main Ship Channel, which is 30 ft. deep and 1 000 ft. wide; the Coney Island Channel, 20 ft. deep and 600 ft. wide; the Bay Ridge, Red Hook, and Navy Yard Channels, on the Brooklyn water-front, 40 ft. deep and from 1 000 to 1 200 ft. wide, this channel being now in the process of extension through Hell Gate with the same authorized depth, although, at present, excavation at Hell Gate is being limited to a 35-ft. depth by 500-ft. width. The Shell Reef Channel on the New York side of the East River, 25 ft. deep and of varying width, is intended to afford useful access to that portion of the Manhattan water-front so that it may soon be improved with appropriate terminals. The Hudson River Channel, on the west side, is 30 ft. deep at Jersey City, 40 ft. deep at Hoboken, and 26 ft. deep at Weehawken. Obviously, the projects for these later improvements should eventually be unified, but, on the whole, it may be said that the channels so far described afford ample facilities for approaching the various portions of the water-front to which they relate.

It will be remembered that in the report of the New York-New Jersey Commission recommendation is made for the development of Jamaica Bay, largely for industrial purposes. The project for Jamaica Bay, adopted many years ago, is a co-operative one, under which the Government agreed eventually to provide an entrance channel, 30 ft. deep and 1 500

* Maj.-Gen., U. S. A.; Chf. of Engrs., U. S. A., Washington, D. C.

ft. wide, protected by one jetty, or, if necessary, by two jetties, and an inner channel, 30 ft. deep and 1 000 ft. wide, is to be provided by the City of New York, the United States to pay such portion of the cost of dredging the interior channel not in excess of 8 cents per cu. yd. The City further undertook to construct certain bulkheads, make certain slips, and create such fills from the available spoil as might be necessary to reclaim the lowlands bordering the Bay and to make them available for terminal development under a plan that had been proposed on its behalf by a technical commission retained for that purpose. At present, the work that has been done on this project is limited to an entrance channel 18 ft. deep and 500 ft. wide, extending inland 8 800 ft. to Mill Basin and, as yet, the City has not been able to fulfill the terms of the original co-operative agreement. Recently, however, the representatives of the City have been in conference with the agents of the United States with a view to securing early and effective action toward the completion of a considerable portion of the main 30-foot channel previously described. The matter is more fully discussed in Document No. 4 of the Committee on Rivers and Harbors, House of Representatives, 66th Congress, Second Session, in which it is pointed out that further action in regard to Jamaica Bay should be deferred until its development as an element in the progressive improvement of the entire Port of New York has been considered and decided, the underlying principle being that any comprehensive plan for the further development of the Port of New York would certainly indicate the relative importance of its various elements, and that Jamaica Bay should progress in accordance with the orderly programme thus laid down.

As far as such a project as Jamaica Bay is concerned, however, it may be of interest to engineers to know that in recent years it has been the wholesome policy of Congress to require greater local co-operation toward paying the cost of main channels and of such protective works as are necessary to insure the integrity of these main channels whenever the project to be undertaken is of a more or less speculative character, as is true, for example, in the case of Jamaica Bay where no commerce exists and where the character and extent of future traffic are, after all, more or less matters of opinion. It may well be that when in the future the larger project for making available the waters and shores of Jamaica Bay again comes up for consideration, Congress will feel justified in asking the community to bear its fair share of the risk, not only by improving real estate, but also by paying a fair portion of the cost of channels which in the end may possibly prove to be none too profitable.

Resuming the enumeration of the existing channels in the Port of New York, the Newark Bay Channel is 20 ft. deep and 400 ft. wide, with a side channel of similar dimensions connecting the central channel with the Port of New York development. At present a project is under consideration for deepening this channel to 30 ft. Some difficulty has been experienced in deciding as to the best policy regarding this particular channel because of the obstructive bridge near its foot, connecting the mainland with the Bayonne Peninsula. This bridge which belongs to the Central Railroad of New Jersey, is now required to be reconstructed under the existing project, but as yet no change has been made, and it is perhaps worth saying that until it is positively

known that this bridge will be changed to permit the easy passage of deep-sea carriers, it would be useless to spend any money in deepening the main Newark Bay Channel.

The remaining important channel is the Arthur Kill Channel, which is 25 ft. deep and 400 ft. wide. This channel is a very busy waterway and, recently, the traffic has been so heavy as to call for a re-examination of its needs. The War Department has recommended to Congress that a project for a channel 30 ft. deep and 400 ft. wide through Raritan Bay and Arthur Kill, to connect with the corresponding channel in Kill van Kull, be adopted at a total cost estimated one year ago (1920), at about $10 400 000.

This summarizes the situation as to the main channels in the Port of New York. The War Department and the Corps of Engineers constantly study and observe traffic and terminal conditions in order that they may be able to appraise intelligently the needs of the ports. Whenever these studies indicate the desirability of greater channel accommodations, either by deepening and widening existing channels, or by extending them and creating new ones, the need will certainly be reported to Congress in ample time to avoid the damage or inconvenience that might result from a failure to take timely action. So far as is consistent with the duty of protecting the National Treasury from unprofitable or unnecessary expenditures, the speaker can safely promise that the War Department will always, in the future as in the past, deal not only considerately but liberally with shipping and with water-borne traffic. When their needs are in the form of an extension of any channel so that additional terminals may be created to supplement existing terminals already fully used, no difficulty will be experienced as far as the Department is concerned in securing a recommendation to Congress that the channels be appropriately enlarged. It is necessary, of course, to safeguard this promise by the statement that its policy is to insist that proper use be made of the portions of the shores of any port to which access has been afforded by the creation of adequate channels, and this insistence may well take the form of requiring that where important sites are occupied by activities not located by necessity on the water-front, these sites be vacated and suitable terminals provided there before the Government is forced to further expense in the provision of channels. This weakness in the development of the Port of New York is well known and is emphasized in the monumental report of the Joint Commission in which attention is repeatedly drawn to the fact that, especially on the two sides of the Hudson River, the shores are used as railroad stations and not for transfer from rail to ship and ship to rail. This evil is especially noticeable on the west front of the Hudson, where practically all the Jersey City front and much of that of Hoboken and Weehawken is so used. What a relief it would be to the Port of New York if these considerable lengths of shore line were available for the construction of modern piers and their adjuncts. It ought not to be regarded, therefore, as unreasonable for the National Government to insist, as was recently done in the case of a South Atlantic port, that all available frontage be properly utilized before extensions of channels are made.

Reverting now to the relation of the War Department to the National port terminal problem, it is probably well known that, in recent years, Congress on frequent occasions, has indicated its view that port and river terminals were essential adjuncts of waterway improvements and that they should be incorporated in any proper plan of such improvements and required to be supplied by the local interests. The extent of the preoccupation of Congress with terminal matters and the importance which it attaches to the creation of proper terminal facilities is shown by the legislation incorporated in Section 7 of the River and Harbor Act, approved July 18th, 1918, which reads as follows:

"Section 7. That hereafter the Chief of Engineers, United States Army, shall indicate in his annual reports the character of the terminal and transfer facilities existing on every harbor or waterway under maintenance or improvement by the United States, and state whether they are considered adequate for existing commerce. He shall also submit one or more special reports on this subject, as soon as possible, including, among other things, the following:

"(*a*) A brief description of such water terminals, including location and the suitability of such terminals to the existing traffic conditions, and whether such terminals are publicly or privately owned, and the terms and conditions under which they may be subjected to public use.

"(*b*) Whether such water terminals are connected by a belt or spur line of railroad with all the railroads serving the same territory or municipality, and whether such connecting railroad is owned by the public and the conditions upon which the same may be used, and also whether there is an interchange of traffic between the water carriers and the railroad or railroads as to such traffic which is carried partly by rail and partly by water to its destination, and also whether improved and adequate highways have been constructed connecting such water terminal with the other lines of highways.

"(*c*) If no water terminals have been constructed by the municipality or other existing public agency there shall be included in his report an expression of opinion in general terms as to the necessity, number, and appropriate location of such a terminal or terminals.

"(*d*) An investigation of the general subject of water terminals, with descriptions and general plans of terminals of appropriate types and construction for the harbors and waterways of the United States suitable for various commercial purposes and adapted to the varying conditions of tides, floods, and other physical characteristics."

A further expression of the policy of Congress in regard to terminals is contained in the River and Harbor Act approved March 2d, 1919, in which the following statement is incorporated:

"It is hereby declared to be the policy of the Congress that water terminals are essential at all cities and towns located upon harbors or navigable waterways and that at least one public terminal should exist, constructed, owned, and regulated by the municipality, or other public agency of the State and open to the use of all on equal terms, and with the view of carrying out this policy to the fullest possible extent the Secretary of War is hereby vested with the discretion to withhold, unless the public interests would seriously suffer by delay, monies appropriated in this Act for new projects adopted herein, or for the further improvement of existing projects if, in his opinion, no water terminals exist adequate for the traffic and open to all on equal terms, or unless satisfactory assurances are received that local or other interests will

provide such adequate terminal or terminals. The Secretary of War, through the Chief of Engineers, shall give full publicity, as far as may be practicable, to this provision."

It will be noted that the Chief of Engineers is required to report annually on the character of the terminals existing in every harbor or waterway under improvement by the United States, and to express an opinion in regard to their adequacy. This requirement, of course, cannot be fulfilled unless consideration is given not only to the character and number of the terminals themselves, but also to the place of each port in the National transportation system, its tributary territory, the traffic it ought to serve, its probable future growth, and the effects, restrictive or otherwise, of existing channel developments. These questions are so important and far reaching that to answer them satisfactorily it has been found necessary to expand greatly the functions of the Board of Engineers for Rivers and Harbors which, until about two years ago, had for its main function the review of projects, active or proposed, for river and harbor improvements. At present, therefore, this Board, under a plan approved by the speaker, is making a close and intensive study of every important seaport in the United States and an analysis of its most useful place in a properly conceived National system. These investigations permit replies with considerable certainty to questions relating to the adequacy of port terminal development.

The special reports called for in Paragraphs *a*, *b*, and *c* of the 1918 legislation have been consolidated in a single report.* This bulky volume is in greater part a compilation of facts relating to all water terminals on waterways now being improved or maintained by the United States. Its principal service to the public, and especially to engineers, is to place before them in authoritative form the many things relating to existing port improvements, which usually are known only in a general way, if at all. For example, it gives to every careful reader a serviceable idea regarding the state of development concerning any port in which he may be interested.

The investigation of the general subject of water terminals, called for in Paragraph *d* of the 1918 legislation, has been made by the Board of Engineers for Rivers and Harbors, and the results are contained in a comprehensive report† by Capt. F. T. Chambers, U. S. N., associated with the Board as expert adviser on terminal matters. The illustrations accompanying the report are numerous and afford examples of nearly every useful type of terminal known to exist. In order to show the scope of this report, the speaker will enumerate the headings, as follows:

Ocean terminals are considered under the following sub-divisions: sheltered location necessary; ports; terminal facilities; tides and floods; anchorage; fore and aft moorings; locks and basins; docks, quays, wharves, and piers; open or uncovered terminals; ground storage for materials in bulk; ocean and inland waterways terminals; other open or uncovered terminals; naval stores; covered terminals for material in bulk; storage for liquor material in bulk; fire protection; grain elevators; covered terminals for miscellaneous or package freight; types of construction; piers; materials for construction;

* House Document No. 652, 66th Cong., 2d Session.
† House Document No. 109, 67th Cong., 1st Session.

examples of pier construction; quays and wharves; warehouses; warehouses for special purposes; railroads; lighterage; mechanical equipment; ship's gear; ship's gear in combination with portable winches and cargo masts; wharf cranes; types of cranes; monorails and telphers; conveyors; slot conveyors; pan and bucket conveyors; chain hook conveyors; portable chain and belt units; gravity conveyors; gravity roller conveyors; piling; machines; fixed elevators; trucks; self-propelling vehicles; tractors and trailers; floating equipment; floating derricks; steam lighters; suction grain elevators; chain belt bucket units for grain; bunkering equipment; portable bunkering units; car floats; repairs and reconditioning; types of dry docks; seaport terminal; planning, including harbors, channels, ship characteristics, tides, available water-front, character of exports and imports, open and covered wharfage, railways, piers, and slips, floor space under cover, railway trackage at water-side, hoisting equipment, railway tracks and roadway at rear of shed, railway yards, disposal of dredged material, quay or wharf construction storehouses, mechanical equipment, justification for transit sheds of large area, port terminal charges; port terminal control; forms of port control, public, private and railroad, railway port terminal charges, public management.

Inland waterway terminals are considered under the following subdivisions: canals and rivers; navigable depths and variation of water level; terminals for waterways of constant level; terminals for handling bulk cargo; terminals for rivers of wide variation of water level.

The 1919 legislation as to the essentiality of having at least one public terminal at each waterway locality under improvement by the United States, is a plain declaration of a belief which has long been held in public places, although not so formally expressed. The idea is sound, but does not go far enough. Every one who has come in contact with the port terminal problem sooner or later has been forced to conclude that perhaps the greatest evil in the situation and one of the principal "National Port Problems" is the undue extent to which the water-fronts of the principal seaports have passed into railroad control or ownership. The effect of such railroad predominance has often been to influence the prosperity of the seaports, some of which have been favored at the expense of others. The situation in this regard is quite fully covered by the Board of Engineers for Rivers and Harbors, in a recent report which relates to the South Atlantic and Gulf Ports, and recommends steps to prevent the railroads from continuing this kind of activity, by compelling them to make rates for terminal services fairly compensatory for the work involved and the use of the facilities concerned. The belief of the Board is, however, that the railroads should be compelled to divest themselves of their ownership of these port terminal properties and that preferably they should pass to public ownership and control.

It may be of interest to quote the closing paragraphs of the report on the investigation of terminal charges at South Atlantic and Gulf Ports by the Board of Engineers for Rivers and Harbors:

"In promoting water transportation, the War Department and the Shipping Board recognize that a primary necessity is the provision of adequate terminals, and they have an interest in securing such changes in existing conditions as may be necessary to establish them. The absorption of terminal charges in the rate for the line haul and their inadequacy render it impracticable for the private terminal to compete with the railroad terminal for through business just as a large mercantile establishment by selling one commodity below cost can destroy the business of a special dealer in that commodity, and still make

a profit on the total business. It is well known that except at a few places where unusual conditions prevail, private terminals cannot be operated at a profit. The situation is somewhat different in respect to publicly owned terminals. Municipal corporations generally have good credit and are able to borrow money at low rates. Even though public terminals may show an apparent deficit, it may well happen that they will cause such growth in general prosperity and in the volume of business as will outweigh any tax burden caused by the terminals.

"To permit the free flow of commerce through our ports, the obstacles in the way of creating modern terminals must be removed, and since the carriers themselves cannot be expected to initiate the necessary reforms, prompt steps should be taken by the United States. Two remedies have been suggested: First, a scale of terminal charges sufficient to cover the actual cost of the service, plus a reasonable return on the investment. This would enable private terminals to operate if the railroads were obliged to pay them such charges for services actually performed. Second, the discontinuance of the practice of absorbing terminal charges in the rate for the haul. The latter remedy has been widely advocated, but clearly presents some difficulties in its application, and necessarily implies a complete revision of all rates to and from water points.

"In some cases an effective remedy would be the ownership and operation by the State or municipality of all water terminals used for public transportation purposes, including a belt-line railroad affording connection with all wharves and with all railroads serving the port. With the switching, wharfage, handling, and storage charges, in the hands of the State or municipality, every terminal within the port might expect equal treatment, and the responsibility for providing adequate facilities would rest squarely upon the community itself. This remedy is not practicable at many localities, however, owing to the extensive occupation of the water-front by private interests.

"The difficulties confronting the solution of the problems herein considered are fully recognized, and it is obvious that decision as to the wisdom of any plan for correcting existing conditions should be reached only after the most searching investigation of its effect upon the movement of traffic and the relationship between competing ports. The matter is of such importance to the commerce of the country and the success of the merchant marine, however, that no difficulties should be allowed to stand in the way of securing an adequate remedy."

On March 25th, 1921, the Secretary of War brought this situation as to inadequate or unfair terminal charges to the attention of the Interstate Commerce Commission. As this letter is an impartial summary of the situation, it seems of sufficient interest to be read in its entirety, and is as follows:

"By reason of the war emergency the country has been provided with a large commercial fleet upon which a very large sum already has been expended. It is indispensable to our safety and prosperity as a nation that this fleet operate successfully and economically in competition with the vessels of our maritime and commercial rivals.

"Indirect and direct charges of a ship in port run from $1 000 to $5 000 per diem, and every day spent by each ship in port in excess of the minimum time required to load and discharge cargo, and to take on fuel and supplies, is a waste, which summed up for the entire fleet amounts under present conditions to millions of dollars per annum. Ships earn money only when they are kept moving with profitable cargo. Efficient operation, therefore, requires that the days spent in port be the fewest practicable.

"With the object of promoting, encouraging, and developing ports and transportation facilities in connection with water commerce, Section 8 of the Merchant Marine Act authorizes the Shipping Board, in co-operation with

the Secretary of War, to investigate territorial regions and zones tributary to ports, in order to determine what rates, charges, rules, or regulations should be established, and, in case changes are found necessary, to submit its findings to the Interstate Commerce Commission for such action as the Commission may consider proper under existing law. The Board of Engineers for Rivers and Harbors on behalf of the War Department has therefore been investigating the subject of port facilities, and both the Chief of Engineers and the Board are convinced that the success of our commercial fleet is largely dependent upon the economical operation of our ports.

"The results of the above investigation have been compiled by the Statistical Section of the Board of Engineers for Rivers and Harbors and are shown in the attached paper, which also contains excerpts from the various laws assigning to the War Department and the Shipping Board duties in connection with port regulation and port development. In view of the evidence presented in this compilation, it is requested that the subject of port charges and practices at South Atlantic and Gulf ports be considered with a view to the initiation of the necessary reforms, so that commerce may flow through our ports with the greatest possible speed and the least friction; or, in other terms, at the least expense to both the shipper and the ship owner.

"The Chief of Engineers points out that there are three forms of terminal control. These are (*a*) public (State or municipal); (*b*) railroad; and (*c*) private; and at none of our important ports is the control absolute under any one of these three heads. San Francisco and New Orleans have the nearest approach to complete public control, but at all of our important ports there is some railroad control, and at many of them there are also private terminals. Under present conditions of railroad operation, the railroads have no direct incentive to build or to operate terminals such as would turn the ships around in the least practicable time, and, even should such incentive exist, they are not now financially able to provide the costly wide piers and the expensive mechanical equipment necessary to the greatest economy. As will be seen * * * the tariff charges for handling cargo over the railroad terminals at practically all of our South Atlantic and Gulf ports are from one-quarter to one-half the actual cost of performing the work and this is the amount that the railroads allow private terminals for such service performed by them. Under such circumstances private terminals now in existence do mostly a warehousing business, or handle local freight only. They cannot exist on the railroad divisions for through overseas business. Private capital cannot therefore be attracted to invest in such terminals, nor can the largest cities be expected to construct modern terminals, if, as sometimes happens, the situation created by the railroads is such that it is certain in advance that an adequate return cannot be had with which to amortize the bonded debt and that the indirect gains are so seriously restricted as not to counterbalance this direct loss.

"Obviously, it would be advantageous to the public to have full freedom in the choice of routes over which its commodities may be transported. Such choice is now, however, limited and one of the limiting conditions is the fact that the route that otherwise might be preferable may have at the terminal port facilities such as wharves, transit sheds, storage warehouses, and the like whose capacity is merely sufficient to care for existing business or whose equipment may be poor, antiquated, inefficient, or uneconomical. Such restraints upon the adoption of the economic path for moving traffic should, in the general interest, be removed and the opportunity should be afforded all concerned to create, with reasonable prospect of adequate return, such port terminal facilities as seem needed and desirable. The only way in which this can be brought about is to put all such terminals upon a proper basis. The difficulties of the problem are no doubt considerable, but it is believed that this can be done, in some cases by revising the terminal tariffs so as to be reason-

ably compensatory for the service actually performed, thereby permitting privately owned terminals to be created and operated. In general, however, the ownership and operation of all terminals by the local public authorities or by the State constitute the best solution and this course should be adopted wherever possible.

"I would ask that the facts herein presented be considered with a view to the early application of such remedies as may promote the end in view, namely, the reduction to a minimum of the cost of transporting the goods that enter into our water-borne trade, both foreign and domestic."

As a result of these representations the Interstate Commerce Commission has held a series of hearings at all the ports included in the investigation, the first having been held at Norfolk, Va., on September 9th, 1921. It is not unreasonable to expect that the final outcome will be to place the port terminal situation as to charges on a sounder basis.

It will be observed that the War Department and the Corps of Engineers believe it to be for the best interest of the public that water-front improvements be publicly owned and operated, but in this matter of public operation it is important that caution be observed not to permit such operation by the political agencies sometimes utilized by city and State governments, which would be to the serious detriment of seaport terminals. The form of public operation which the War Department favors and which the speaker strongly advocates is that under which some form of port authority exercises control on behalf of the public, similar to the English so-called "Port or Harbor Trust." This body is dominated by representatives of the shipping, commercial, and business interests of the port and the purely political members constitute a small minority.

One of the greatest obstacles to the progress of American shipping business and to the promotion of the export and import traffic is the lack of unity of management. In this respect, Americans should take a leaf from the book of their British competitors, who have made this subject a study for many years of successful maritime business. Every considerable British port has a really unified management.

Forms of Port Control.

In general, it may be said that port terminal control is of three kinds: (1) public; (2) railroad; and (3) private.

(1).—*Public Control.*—This is best illustrated by the practice of such ports as Hamburg, which is a commercial State, and of London, Liverpool, and Bristol, England, which more nearly represent what we should endeavor to attain in the United States. The Port of London suffered for many years from the internal competition of a number of separate dock companies within the port. It was not until July, 1908, that the entire port property was taken over and put under the London Port Authority, competition within the port thus eliminated, and the port as a whole put in a position to direct its energies to competition with other ports. This Port Authority is called in England a "Trust", not as this word is generally used in the United States, but in the sense of a corporation operating without profit for the public benefit. This does not mean that port charges are not assessed, but only that the revenues

obtained from such charges are devoted exclusively to the interest of the port terminal, and not, as in the City of New York, to such extraneous matters as the cleaning of the city streets and other items of city maintenance. In other words, where New York devotes a considerable part of its revenue from the city-owned piers to general city purposes, London devotes its tolls to that part of the welfare of the community which is bound up in the promotion of its shipping trade. Another organization called "The Trinity House" is responsible for the lighting and buoying of the river. The Metropolitan Police are the guardians of the port, and the Corporation of the City of London supervises the sanitary conditions with regard to shipping.

The Port Authority is empowered to collect tolls on ships and goods, and has full jurisdiction over the various docks and terminals. It is constituted as follows: Appointed members, 10: one by the Admiralty; two by the Board of Trade; two by the London County Council (being members of the Council); two by the London County Council (not being members of the Council); one by the City Corporation (being a member of the Corporation); one by the City Corporation (not being a member of the Corporation); and one by Trinity House. The elected members number 18: Seventeen by the payers of dues, wharfingers, and owners of river craft; and one by the wharfingers. In addition, the Chairman and Vice-Chairman may be appointed from outside the membership of the Authority, making the total possible number 30.

The organization at Liverpool is known as the Mersey Dock and Harbor Board. It is quite similar in its constitution to the London Authority, and has 28 members, 24 of whom are elected by the dock rate-payers, that is, persons paying rates and dues on ships and goods only, the remaining 4 being appointed by the Mersey Conservancy Commission, which consists of the First Lord of the Admiralty, the Chancellor of the Duchy of Lancaster, and the President of the Board of Trade. The Board of Trade, unlike the Boards of Trade in the United States, is a National institution corresponding in many respects with the Department of Commerce. In making appointments to the Mersey Board, the effort is made to give the various trading interests in the local shipping community a proportionate representation, and at the present time this is said to work well. Such organizations as those at London and Liverpool may seem to the casual reader unwieldy, but each organization is divided into separate working committees with apparently good effect.

The Port of Bristol is owned and operated by the Municipal Corporation, which thus has jurisdiction over the entire dock system, the control being vested in the City Council, which, for purposes of administration, appoints a sub-committee. This committee employs the executive officials and gives them a free hand in the management. It is declared that politics plays no part in this administration.

(2).—*Railroad Control.*—Some of the ports of England, notably, that of Immingham, are entirely in the hands of the railways. The port terminal is operated as a part of the railway system, and as a means of getting business. In fact, many ports in the United States are operated on this same railway basis, the port terminal charges being nothing, or nominal, wherever the railway is enabled to get business by offering dockage to the ship.

(3).—*Private Control.*—Terminals of this class are operated by private individuals or corporations in the pursuit of their own business in all parts of the world. They may be adapted to the handling of only one product, or to miscellaneous freight. The manufacturing concern may be located at the terminal, and may use its water-front facilities in direct connection with its business only, or, in some instances, may conduct a separate terminal and warehousing business.

General.—It may be said in general that taken as a whole no port in the United States comes under any one of the three previously named headings. In all ports of any size all three methods of administration are in force. It is true that at San Francisco and New Orleans public port authorities are controlled by the State, but, at San Francisco, the Harbor Board confines its activities to the water-front at San Francisco, while the railways have terminals across the Bay at Oakland, on which side of the harbor there are also private terminals. At New Orleans, also, the State Board and the railways have separate terminals.

In some ports it has been the practice to lease the publicly owned terminals to private operators. Although there may be some financial justification for this policy, it seems well to observe some degree of caution in granting exclusive and particularly long-time leases for the use of piers and wharves. The recent experience has been that such exclusive leases may result in less efficient use of the terminals than is desirable for the best interests of the port. A lessee, for example, may keep his pier idle rather than permit its use by an actual or potential competitor, or he may make such high charges as to drive business away from the port. This actually happened in New York during the World War. If leases must be made, they should preferably be in the form of a first call on a berth, leaving to the public port authority the right, when the berth is vacant, to assign to it vessels other than those belonging to the lessee.

At the same time, the prestige of a port depends greatly on the number of regular services that it affords. Liners belonging to such services are most readily identified by the public when their sailings take place from definitely known piers. The system of first call on a berth usually meets this situation adequately, but if it is necessary to promote liner service a limited number of concessions from the rule might be made.

It seems well to repeat the result of the review of the port situation in the United States, as stated in the report of Capt. Chambers, to which reference has previously been made. This review shows:

1.—That there is not, in most ports, a well co-ordinated management and that a well constituted port authority is the first need.

2.—That under these port authorities, comprehensive plans should be evolved, based on principles hereinbefore laid down.

3.—That a port can only be successful when this plan is based on the business available in its tributary area and brings ample railway facilities into the closest practicable juxtaposition with the water-front, with sufficiently wide areas available for cargo classification.

4.—That, with the increased cost of labor, mechanical means, wherever practicable, should be adopted for handling goods, and that such means should be at hand for every kind and shape of package.

5.—That ample railroad tracks should be available close to the terminal for car storage and car classification.

6.—That ample warehouse capacity should be provided, in order that both ships and cars may be dispatched in the shortest practicable time. Too many American ports are lacking in warehouse facilities, or have such facilities at an inordinate distance from the terminal, thus involving cartage, or extra handling, for local railroad haul.

7.—Where cartage is necessarily a feature in the port business, roadways and loading platforms should be provided for the full accommodation of trucks.

8.—That bunkering facilities of such character as to supply the necessary fuel to the ship while handling cargo should be available.

9.—That ample repair and dry-docking facilities should be provided.

No matter how ample the provision of terminal piers, sheds, railways, and mechanical equipment, a port will only succeed under an efficient and well co-ordinated management.

Although this discussion of the general subject of "Terminals" has been from the point of view of the War Department, the speaker feels that in closing he should state that it is the policy and the wish of the Department to be helpful to the people it serves, and in the discharge of the trust imposed and in using the discretion confided by law, the desire is to be liberal and not narrowly technical. Therefore, an invitation is extended for the frank and full discussion of problems connected with the subject, with the promise that they will receive patient and sympathetic consideration.

DEVELOPMENT OF THE SMALLER PORTS

By Frederic H. Fay,* M. Am. Soc. C. E.

As a nation, Americans are slowly coming to a realization of the economic value of their seaports to the country, a lesson learned long ago by their European neighbors and more recently by their Canadian cousins who have been more alert than themselves and by whose example and foresight they may well profit.

Before the World War it was commonly stated that a ton of freight could be hauled 5 miles by water as cheaply as it could be carried 1 mile by rail. With changed conditions, due to the war, this ratio may now be changed. Leaving aside, however, for the moment, the cost of loading and unloading which admittedly constitutes a large part of a transportation charge, it is to-day unquestionably true that freight can be hauled at a given cost a far greater distance by water than by rail. As a nation, Americans should be giving more serious consideration to the importance of water-borne, coastwise traffic, and since the opening of the Panama Canal, particularly to the possibility of greatly increasing coastwise traffic between the Atlantic and Pacific ports. A full development of this domestic commerce by water routes between these two coasts should result in extensive changes in the routing of freight by rail and in the rail-rate structure, stimulate the interchange of commodities between remote sections of the country, and prove of economic benefit to the nation as a whole. Although only in its infancy, the small beginnings which in these abnormal times have already been started in the Atlantic-Pacific coastwise trade, have had a marked effect in certain directions. Low coastwise rates have been established which, in some instances, are less than half the transcontinental rail rates, and the results thus far give promise of the larger results to follow when business has returned to normal conditions.

Until recently, the development of American ports has been left very largely to private interests, usually to the railroads which naturally have made their developments with a view to their own immediate gains and without regard to the larger advantages to the public as a whole through the unification and co-ordination of the development of a port as a single unit. The American public is gradually awakening to an appreciation of the importance of public ownership or control of port facilities and of the commercial value of ports, especially as agencies in foreign commerce. Efforts toward public port development should not be concentrated on a few of the larger ports and primarily for purposes of foreign commerce; public attention should also be drawn to the benefits to be gained by the development of the smaller ports as well, not having in view foreign commerce alone, but also the need of stimulating water-borne domestic commerce and the economies and benefits resulting therefrom. That part of the Engineering Profession concerned in port-development work has a public duty to perform in giving serious study to the situation as it exists at the smaller ports and of acquainting the public with the facts as they find them.

* Cons. Engr. (Fay, Spofford and Thorndike), Boston, Mass.

Economic Value of the Seaports.

A community located on a busy harbor enjoys many special advantages. Marine carriers make large capital outlays in connection with their terminal operations. They buy coal, provisions, and other supplies from local dealers; pay substantial sums in wages to longshoremen and freight-handlers; spend money for repairs and employ towing companies and pilots. Even at many of the smaller ports millions of dollars attributable to port activities alone are distributed annually in the port community.

In a larger way, however, the port is the servant of the interior. For every ton of local freight shipped to and from the port community itself, there are usually many tons shipped to and from the district immediately tributary as well as from more remote inland territory. This indicates the true relationship between the seaport and its hinterland. The port serves the interior in the latter's dealings with coastwise and foreign ports, and provides the smoothest mechanical and commercial means for the movement of inland freight to and on the water. Its development calls into life new water lines and betters the service of existing lines, and its merchants find new markets for inland products.

A well-developed port is of indirect benefit to city, State, and nation, and its development should not be left in private hands, but should be under public control and participated in jointly by municipal, State, and Federal governments.

The principle of Federal aid has long been established through the assumption by the Federal Government of the work of dredging and improving harbor channels, harbor protection, and the provision of aids to navigation.

More recently State agencies have undertaken the building and development of water-front terminals, the reclamation of water-front lands, and even the dredging of harbor channels, to supplement the improvements made by the Federal Government.

In a few instances municipalities, at their own expense, have provided extensive water-front terminals; in others, they have co-operated with State agencies in such undertakings, as, for example, in acquiring water-front sites on which State funds are spent for pier construction.

The public is coming to a general recognition of the soundness of the principle that the seaports are an important National asset and, as such, should be under public, not private, control; and, further, that Federal aid should properly be given to the improvement of the water facilities of a harbor, while States and municipalities may properly work together in providing water-side facilities and necessary improvements on land.

Requisites of a Port.

It may not be out of place to consider briefly the chief requisites of a port, since the engineer must have these fundamentals in mind when studying the problems of any port, large or small.

Water Facilities.—There must be a good harbor, well sheltered, and free from ice; a natural harbor, if possible, or, at least, a location such that an harbor may be developed at moderate expense. The harbor should have

natural deep-water channels, or else a bottom such that adequate channels may be dredged and maintained at reasonable costs, and should preferably be in close proximity to the open ocean with a safe and direct approach channel and, if possible, an absence of an outer bar.

Rail Facilities.—On land, there should be adequate railroad facilities, not only locally throughout the district immediately tributary to the port, but also trunk-line connections to more remote points in the interior of the country. At the port itself, there should be adequate railroad terminals, including classification and storage yards and supporting yards in close proximity to the water-front piers. Important for the success of a port are belt-line rail facilities for the interchange of freight between the several roads and for bringing freight from each railroad to each pier, and fortunate is the port where such facilities exist or can be provided at reasonable expense.

Pier Facilities.—The pier is the connecting link between rail and water carriers. Piers should have transit sheds sufficiently large for the assembly and rapid handling of cargoes. Present-day ships call for piers of large size and larger shed capacity than those commonly built in the past. There is general agreement as to the importance of railroad connections to piers, but many port authorities, shippers, and steamship officials in the United States have been slow to grasp the importance of equipping piers with adequate, modern, mechanical apparatus for the rapid handling of freight.

In addition to the general factors already noted, recognition should be given to the importance of good highways throughout the territory immediately tributary to the port. The motor truck has its legitimate field in the inter-urban transportation of high-class package freight, and by its use many inland industrial communities may have connection with the seaport more cheaply than by rail.

It is obvious that a port situated at the mouth of a navigable stream has the added advantage of water transportation as well as rail connection with its hinterland.

Where advantages such as those already outlined exist, public authorities should give serious consideration to the possibilities of their proper utilization, and this is particularly true of many of the smaller ports. Europeans have realized more keenly than Americans the importance of access to the sea, and, in many instances, enormous sums have been spent in overcoming natural obstacles and in making seaports out of inland, or semi-inland, cities, as at Manchester, Glasgow, Amsterdam, Rotterdam, and Hamburg.

It is in connection with the smaller ports particularly that the engineer should live up to his duty as an economist, study each local situation with critical analysis and breadth of vision, and be a pioneer in calling public attention to the possibilities that lie before us.

Danger of Concentration in a Single Large Port.

In the United States the tendency has been to foster the development of the Port of New York which, for years, has handled approximately 50% of the country's foreign commerce, and ignore the natural advantages of, and the importance of developing, many of the smaller ports. Americans may well

ask themselves the question whether it is a wise policy for the country as a whole to have so large a proportion of its commerce tied to a single port.

Less than two years ago, the Collector of the Port wrote of conditions at New York* as follows:

"We are accustomed to speak of New York as the greatest commercial port in the world. So it is. To-day its water-borne commerce, foreign and coastwise, is greater than that of any other two ports in the world; but that is no reason why it will continue to hold this place for all time. * * * When the pressure of war traffic came upon us the port of New York 'broke down', or so nearly broke down that it was a matter of National distress and alarm. Along the extensive shore line of the inner harbor there was ample space for handling all the traffic the war sent to our port; but only a part of the harbor shore line was available. There were not piers enough to accommodate the vessels, and most of the available piers were too small, inaccessible, improperly equipped, or being used for some purpose necessary for the domestic demands of the city."

In war time, the successful blockading of this one port by a strong enemy fleet would be a tremendous handicap. At any time, local conditions may precipitate a strike of longshoremen, or freight-handlers, with paralysis of shipping, as New York well knows by recent experiences. Only last winter (1920–21) the influx of immigrants at New York was so great that the immigration and quarantine facilities of the port were unable to handle them, and it was necessary to divert ships to other ports to land such passengers. The cost of handling freight is enhanced by lack of belt-line railroad facilities, by the necessity for lighterage to supplement the roads, and by lack of modern piers equipped with modern freight-handling facilities. Furthermore, the values of New York water-front property are so great as to place a substantial over-head burden in the carrying charges on the investment in water-front terminals. All these factors tend to enhance the cost of handling freight in New York and the question may well be asked whether a considerable proportion of the business now passing through that port could not be handled cheaper, with consequent economic saving to the nation, at some of the smaller ports.

Efficiency and economy must be applied to the nation's business if it is to take its full part in world affairs.

Advantages of Development of Smaller Ports.

Instead of putting so many "eggs in a single basket", which may come to smash at any time, as has been proven at New York during and immediately after the World War, is it not better to get a diversion of commerce through other ports possessing good, if not equal, natural advantages, and to awaken in the public mind a realization of the National, State, and local benefits, arising from suitable public development of some of the smaller ports?

The development of smaller ports means a diminution of labor troubles and less likelihood of strikes having such serious effects on water-borne commerce. Such development means not only the building up of cities where the ports are located, but also the districts tributary thereto and a more even

* "New York's Endangered Commercial Leadership," by Byron R. Newton, Collector of the Port of New York, *The Street*, December 31st, 1919.

distribution of prosperity throughout the country at large. Americans have been too much inclined to consider port developments only in the light of foreign commerce, and have ignored the advantages of port development in increasing and cheapening domestic commerce and in lessening the cost of living. In the smaller ports, the cost of development is substantially less than the provision of equally good facilities in a large port like New York. Water-front properties are relatively cheap. Belt-line rail connections are usually more readily provided, if they do not already exist.

To-day, large industries are coming to realize the disadvantages of concentration in the larger cities and the advantages to be gained by locating their plants in smaller communities where better living and labor conditions are found. The development of smaller ports to cheapen transportation to and from smaller communities, both on the seaboard and in the district tributary to the port, is of direct concern to industries which are seeking to develop plants in the smaller cities and towns. This tendency toward distribution rather than concentration is a helpful one for industries and the country as a whole, and makes necessary more than before serious consideration of the need of development of smaller ports to handle not especially overseas traffic, but, primarily, coastwise traffic.

Port Development at Public *versus* Private Expense.

The proper development of American ports is to-day a vital problem. With only a few exceptions, ports in the United States were originally developed by railway or other private interests, and there is ample proof that, in most cases, the individual interests have failed properly to develop and co-ordinate the water-front facilities. Usually, the development has been narrow and selfish, and each railroad naturally has looked after its own individual interests. The recent trend of development has demonstrated plainly that the port must be considered as a whole, with the railroad and other terminal facilities co-ordinated so that they develop the port and the territory tributary to it in the most economical manner and on the broadest possible scale.

Where port development has been by railroad agency alone, it has naturally progressed slowly and, in general, only with the assurance that it would prove to be a paying investment. The tendency until recently has been for each railway to attempt to secure for itself the most advantageous location for its wharves and docks, and then to throttle the development of the port as a whole by setting up artificial barriers through the medium of switching charges, absorption of wharfage and handling charges, etc. As a result, many ports have become in reality a collection of several small ports, each serving as a terminus for an individual railroad, interchange of traffic between various parts of a harbor being rendered both slow and expensive.

A study of North American ports where such facilities are publicly owned or controlled shows that such ports have been a success in every case and this is obviously true for some of the notable ports of Europe. Not only has the operation of these terminals proven the investment to be sound, but the ports have been distinctly benefited by public control. Discriminative railroad practices have been eliminated, more flexibility of operation has been assured,

and commerce has been increased, due in large measure to the greater opportunities for expeditious and cheap handling of traffic.

No private party can be expected to make the large expenditures required for adequate port facilities. These must be made by the public, since States and cities can command a lower rate of interest and will benefit not only from a direct return, but even more largely from the indirect return which increases the business and the prosperity of the city and State in which the port is located. Private parties must consider the cost of water-front terminals purely from the standpoint of direct and immediate financial return, sufficient not only to pay carrying charges, including depreciation, but to return a reasonable profit to the investors. On the other hand, the community may very properly find the greater part of its profits in indirect returns, such as the prevention of the port from being throttled by its more active competitors, increase in commerce, and the promotion of the welfare and prosperity of the city and of the State at large.

Portland, Me., as Typical of the Smaller Ports.

Portland, Me., is a good example of one of the smaller but important ports the development of which has long been neglected, but where public sentiment has been aroused. The needs have been recognized, and the State and the municipality are co-operating toward a modern development. Portland possesses a harbor which, from the standpoint of natural advantages, is one of the best in the United States. Although not comparable with that of New York in size, it is of ample area with a natural deep-water channel and with no bars at its entrance. The harbor is well sheltered, in close proximity to the open ocean, with a channel so direct that steamships making regular calls dispense entirely with pilots and enter the harbor at any time of day or night, at any season of the year, under the direction of their own officers.

Portland is the Atlantic terminus of the Grand Trunk Railway and is the natural winter port for the Dominion of Canada. It is also a terminus of the Boston and Maine and the Maine Central Railroads, and is the nearest port in the United States to the United Kingdom and Europe. That the Federal Government has considered it to be one of the important Atlantic ports is shown by the fact that the harbor has been heavily fortified. During the World War, troops and supplies were shipped therefrom to the full limit of the existing water-front terminals.

Up to the present time, the only piers accommodating overseas shipping were those of the Grand Trunk Terminal; and, except for certain other wharves owned mostly by railroads and equipped for handling such bulk freight as coal, china clay, and sulphur, the wharves are obsolete and relics of the days of sailing ships when Portland had an extensive trade with the West Indies.

Recently, however, the need of increased water-front terminal facilities has been keenly felt. Certain steamship lines which have sought to establish themselves have been unable to do so on account of the lack of facilities for the accommodation of their ships. Only last winter (1920-21), the North Atlantic and Western Steamship Company, the boats of which, engaging in

the Atlantic-Pacific coastwise trade, had been berthed during the summer at the piers of the Grand Trunk Railway Company, found great difficulty in securing accommodation during the winter months, at which time the Grand Trunk Terminal is used to capacity, and succeeded in placing only a few boats at one of the Railway Company's piers through special arrangement with that road and because the Company's business last winter was not at a maximum.

Through the instigation of the Portland Chamber of Commerce, an agitation was begun which has resulted in the starting of further development through co-operation of city and State. The city has just provided the site of the first of a series of publicly owned piers, and the State is now about to construct such a pier alongside the Grand Trunk Terminal. Unlike many other ports, Portland already possesses a belt-line railroad connecting all the railroads entering the city, and the new State pier is located on this belt line so that freight at the pier will be handled on equal terms to and from the railroads. The State and the city are jointly embarking on a policy of port development with the idea not only of providing facilities for increased coastwise business, but also of increasing overseas commerce. The Maine Central Railroad connects with the Canadian Pacific Railway of Canada, which road it is understood has for some time desired entrance into Portland, and this entrance will be assisted by the building of the State-owned terminal.

Portland possesses a location which is unique among the North Atlantic ports in that through the Grand Trunk and Canadian Pacific Lines, it is a natural outlet, especially in the winter months, for territory extending as far as the Canadian Northwest; and because of the United States connections of these two roads, it is a logical outlet as well for the midwest territory of the United States bordering on the Great Lakes. Considering that the present tendency of Federal regulation of the railroads within the United States is to avoid competition in rates and to permit only competition in service, and, further, that Portland is served by Canadian lines which are not subject to regulation by the United States Government, it would seem as if it had possibilities which no other Atlantic port in the United States possesses, for competition in rates and the securing of business.

It is believed by the people of Maine that the development of this port will stimulate the industrial and agricultural growth of the entire State, especially since the State has available a large amount of undeveloped water power which, in these days of high priced coal, may be economically utilized to provide cheap power for industrial uses.

Administration of this new publicly owned terminal the construction of which is to be begun in the latter part of 1921, is in the hands of a board known as the Directors of the Port of Portland. The Board is composed of five members, one of whom represents the city, the others representing the four Congressional districts of the State. The people of Maine, and the Directors of the Port of Portland in particular, keenly realize that their obligations do not end with the provision of adequate, modern, water-front facilities, but that when these facilities are provided and before their completion, active steps must be taken to sell the port to their community and to the country at large.

RELATION OF WAREHOUSES TO PORT DEVELOPMENT

By M. A. Long,* M. Am. Soc. C. E.

The speaker will confine his remarks to his twenty years of experience in railroad work and his study of the warehouses of the different railroad companies, with relation to their inland, lake, and terminal ports.

For instance, at Cincinnati, Ohio, there is a railroad warehouse practically ¼ mile long. Why did the railroad company build that warehouse? Because, if it had not, it would have been compelled to enlarge its yards and buy more cars, using those cars for warehouses in which to store merchandise. By building that warehouse the company saved the expense of additional cars and yards, but a better reason for its construction was to attract business to the line which it had not enjoyed before. The merchants along the line of that railroad also store in this warehouse—advertising it as their own, for that matter—and then ship in small quantities from it to their customers along the line, or along other lines in the adjacent territory. The construction of that warehouse saved these manufacturers the necessity of building warehouses of their own in which to store the surplus which, particularly in seasonal business, they usually have.

If this is true at Cincinnati, is it not true of every seaboard port? Anybody going through New Jersey, and seeing the number of cars on the railroad tracks there, cannot but wonder why the railroad companies do not have warehouses in which to store goods, instead of storing them in cars which are expensive and while being used as warehouses do not earn any revenue, but show a loss. Each year, the railroad companies are compelled to buy more cars and build more tracks to keep up with expanding business. The remedy for this, and this applies to every port, is the construction of a series of warehouses. The speaker is quite sure that if they were built, the manufacturers of this country would use them and so would foreign merchants.

If a firm in any foreign country, doing business in America, had a surplus of goods, knowing that it could dispose of them to advantage in America, and knowing also that there were warehouse accommodations at one of the terminal ports, it would be to the advantage of that firm to ship them, using the warehouse company as its agent for local distribution; or, if its business was seasonal, ship to the warehouse to hold until it had proper opportunity to market its product. There will be a great deal of business of that character as soon as warehouses are built. Of course, there is a reason for all things, and the demurrage rates charged, or rather not charged, are the factors governing the warehouse situation at the ports. The following indicates some of the comparisons between rates charged on foreign and domestic freight. Let a firm ship a carload of merchandise to an inland port or city, after 48 hours' free time demurrage will have to be paid at the rate of $2 per day, for 4 days, and $5 per day thereafter. Suppose that same carload was being shipped to London: if it is shipped to New York on through bill of lading, 15 days' free time are allowed; if it is shipped on con-

* Pres., The M. A. Long Co., Baltimore, Md.

signment 10 days are allowed; for the first 20 days after the free time expires, 1 cent per 100 is charged, and for the next 10 days 3 cents per 100, and it is understood that a lower rate is now being put into effect. Thus, it is evident that, while a local merchant can well afford to pay for handling and storage warehouse charges, one dealing in foreign business does not have to pay such charges, because it is cheaper to use the railroad car as his warehouse.

It has been stated that it costs more to handle a ton of freight in the New York terminal than it costs to transport it by rail from New York City to Pittsburgh, Pa. That is true, and it shows that the railroad companies make their profits from transportation and not from terminal handling. If this statement is correct, the railroad companies could well afford to sell their terminals to the cities, providing they were guaranteed no loss of the business they had built up at a great cost; and it would be very hard indeed to estimate the relative value of a strategic location in a port, as compared to one not so favorably located.

In regard to railroad piers, the speaker has found from experience that they are seldom filled. In fact, in a publicly owned or operated port, ship schedules can be arranged so that those piers will be working to capacity. The speaker has known a time when the railroad piers would not average one vessel per week. That does not pay, and it is necessary to haul a great many tons over the railroad to make up for this terminal loss.

The Baltimore and Ohio Railroad Company contemplated, and made plans for, a pier and warehouse development at Tompkinsville, N. Y. It was not built, however, at the time it was being considered, because the financial market was not favorable. The Company then learned that the city might take the site and one thing and another led to the postponement of the development, and now the city has taken the site. This is only one case, but, in general, it shows why the railroads have not built modern terminals and warehouses at the ports to provide for future business.

Recently, a railroad man said to the speaker, "We have to build more terminals; it is costing us $1 000 on per diem charges". In other words, the cars from various sources are shipped to this road, because this company has arrangements with other roads not reaching the seaport, to handle their cars, and so many carloads were held on consignment in its yards that the per diem rate which had to be paid to the other roads amounted to $1 000.

If the cities or the public owned the terminals, they would be adequate, the railroads would not have the excess terminal charge, and, with adequate terminal warehouses, they would not have to provide so many cars.

In going through his files, the speaker found a reference to the comparative cost of building cars as against building warehouses. For example, take the Locust Point Yard of the Baltimore and Ohio Railroad Company, which has a capacity of 2 500 cars. There has not been a day in the speaker's experience with that railroad, in which that yard was not, as railroad men term it, "chock-a-block". For $1 600 000 a warehouse, including aisleways, mechanical equipment, etc., could be built to house the cubic contents of those 2 500 cars, so that it would work in with the yard and piers. The cars and land are worth $5 000 000.

If each of ten railroads was to build two of these warehouses, it would be equivalent to building 50 000 cars, as it would release that many cars now tied up in yards due to lack of storage room. Without property or tracks, the cars would cost approximately $100 000 000, while the warehouses could be built for $32 000 000.

The railroad companies are discriminating against the domestic as well as against the export shipper, and have done so for years past, in that they allow their cars to be used as warehouses, and that is the reason the warehouses are not built. It is easier for a shipper to ship on a through bill of lading and get that 15 days' free time, with the hope that a vessel will be available and that satisfactory shipping rates can be arranged before it expires, than to pay handling charges in the warehouse. The value per car and space in a yard is calculated to be $1 500. Interest, maintenance, and depreciation charges on the car and tracks are estimated at $172, while if the same carload is placed in a warehouse on the same basis of interest, maintenance, and depreciation charges, it will cost only $61.

Assuming that the average load per car is 25 tons, the annual revenue, on a storage basis, is $115, or a loss of $57 per car per year, if merchandise is stored in the car, and a profit of $54 per carload, if it is placed in the warehouse.

Since the Locust Point Yard is reasonably full of cars at all times, the speaker has used the yard capacity on a yearly basis for estimating. However, all material would not be stored a full year, and after deducting the handling cost, the revenue would be nearer $45, or $112 500 net profit, for the warehouse, against a loss of $142 000 per year, if stored in cars. These figures are general, but they are relative. The earning value of the car in service is not taken into consideration; the comparison is based on its use as a storage warehouse.

The value of the increased capacity and the removal of the necessity on the part of the railroad companies of buying high priced property in order to increase the capacity of their yards, with the likelihood of adding to congestion, are items which count for more than the actual earnings figured on a tonnage basis; and by keeping the cars more actively in use, the miles per car per day will be materially increased. This, of course, would mean greatly increased revenue, and, after all, the public pays the bill, and if the railroad companies could be relieved of excessive terminal charges, they would be in better shape to accept a reduction in freight rates, in which the public is so much interested at this time.

Take New York City as a concrete example, and assume that it will have its usual normal growth for the next ten years. Can any one imagine what it will mean to enlarge the yards and the cost of additional cars necessary to take care of the additional business? Now is the time to start building warehouses in order to prevent this necessary and expensive expansion.

Relative to the matter of warehouses, about three months ago, some interested parties had an opportunity to get a large manufacturing concern to locate at Baltimore, Md. It was practically all arranged, when, in figuring its operating cost to the *n*th power, the company found that Baltimore did not have proper warehouses for certain vessels, or rather certain ship lines, which were handling the raw materials that it wanted from Europe. This

meant that it would be necessary to ship those raw materials from New York to Baltimore to be manufactured, and have them shipped back again for distribution. Therefore, Baltimore lost that enterprise, and New York got it, because the latter city had a greater percentage of warehouses of that character, and also because it had the shipping lines carrying the raw material. This example is a point in favor of the better terminal, and is the strongest argument that can be brought home to engineers on this subject. There should be adequate terminal warehouses built at every seaport.

FUNCTION OF PORT TERMINALS AS CLEARING AGENCIES

By J. Rowland Bibbins,* Esq.

The United States Chamber of Commerce is deeply interested in, and is organizing to study more intensively and on a National scale, the transportation problems of the country as a whole. The speaker, therefore, will confine himself entirely to one of the broader aspects, as he conceives them.

Four distinct aspects of the subject have been outlined for discussion: First, the technical design, which relates to adequacy, capacity, and efficiency in technical problems, and which any experienced engineer can work out, given the problem of equalizing the capacity of main lines, terminals, and ships, such as will be necessary to handle the business of a port. The second aspect is that of administration, covering executive policy, service charges, co-operation with other transport agencies, development plans, etc. The third aspect is the merchant organization, a term happily devised by Dr. McElwee, covering such functions as banking, warehousing, forwarding agencies, etc., all relating to the merchant business of the port. Fourth, and most important, is the aspect of the port terminal as a gateway—the gateway of the interior. It is the funnel mouth, the clearing house for the nation's business with foreign lands, too often complicated by local business with which it has no relation. The gateway controls the production and the economic development of the interior in a manner often lost sight of in discussions of technicalities.

Commerce is interested in developing economical gateways and keeping them open and unobstructed. Commerce regards transportation as a unit element in the cost of doing business, that is, of distribution. Commerce pays the entire transport bill and does not single out any particular element, such as the port terminal charge, on which to concentrate its demands, unless conditions arise which retard, obstruct, and render the transaction of business unnecessarily costly or hazardous. The thought which the speaker wishes to convey is that in this discussion the total cost of transportation must be kept in mind, from the origin to the final destination of shipments. This may involve five or ten re-handlings, or even more for small lots, namely, from the producing interior, through the collecting agencies, the rails, through the terminal agencies and warehousing, the ocean carriers, through the foreign terminals, and distributing agencies; and *vice versa* on imports. This is the complex problem that confronts commerce, and, of course, the port terminal is an important element in that whole problem. After all, the essential criterion of all transportation is based on two things—Time and Cost, and these elements are involved in every branch of the transportation industry, representing an investment of approximately $50 000 000 000.

Back of these various coastal gateways is a great producing area of 3 000 000 sq. miles (with an additional area of 1 000 000 sq. miles in Canada which is closely associated with that of the United States). It is said that only 5% of the total business of the United States is with foreign countries, but the speaker suspects that 25% of the raw products flow through the ports.

* Mgr., Dept. of Transportation and Communication, U. S. Chamber of Commerce, Washington, D. C.

This internal production from farm, mine, and factory has grown up through long years of development and had adjusted itself to the pre-war plan of rates, routes, terminals, business organizations, and manufacturing locations (such as Gary, Ind.). The war dislocated the whole economic plan, that is, the relationships between location of producing centers, transportation costs, and distribution costs. Years are required for an industrial system to readjust itself to essentially changed conditions. If this dislocation continues, the future may force industry to gravitate to the seaboard in order to meet foreign competition. The truth of this statement appears in the great demand for a reduction in export freight rates from the far interior; the demand does not come from seaboard points. Therefore, unless the gateways—and by this the speaker means not only the water gateways, but the internal rail gateways as well—become so highly organized as to overcome this handicap of long and expensive interior transportation, a complete realignment of industry in the United States may be witnessed.

Commerce gravitates along the line of least economic resistance; in fact, if one can conceive of commerce and tonnage as water running down hill, one can visualize the Economic Divide—a hypothetical mountain range running diagonally across the country, determining which way that water-borne tonnage should naturally flow to foreign ports, that is, whether it should flow east or south, or to the west. It is not difficult to equalize the water and rail rates from a given producing interior region to a given foreign destination to locate definitely this Economic Divide.* Temporarily, the Divide may be diverted by sentiment or precedent; that is, if logic and the true cost of service dictate a certain route for internal tonnage to its foreign destination, and if it is found that the tonnage actually flows by an entirely different route, this may be the result of historical precedent, regional sentiment, preponderant rail development, or shipping policy. Eventually, however, trafficways for this interior production, in order to become permanent, must find and rest on their economic justification. Likewise, the gateways, in order to enjoy permanency and to meet growth, must retain their efficiency; and the gateways are the keys to the situation.

How shall this demand for continued expansion be met? Analyze the general business indices† of typical cities of the United States and it will be found that the general business which concerns transportation doubles in from 8 to 13 years. Cleveland, Ohio, is an example of a progressive community doubling its business in 8 years.

Now, even a modest port plan would require at least 5 years to organize and start *de novo*. It might easily take 10 years or more to complete the major elements, yet the ton-mileage of the United States doubled in 13 years, just prior to the World War, and its tonnage has increased as fast as the fourth power of the population. Here, then, is some measure of the problem

* See the speaker's paper, "Economic Lines of Gravitation for Overseas Movement", Am. Assoc. of Port Authorities, 1920; *Engineering News-Record*, 1919.

† Such as imports and exports, railroad tonnage, shipping tonnage, warehousing, bank clearings, post-office receipts, industrial output, auto-registration, electric railway traffic, school attendance, telephone traffic, etc.

of growth which concerns every seaboard municipality—every port terminal—and the widespread lack of appreciation of this rate of growth is responsible to a great extent for the lack of development. In other words, a different conception of port-terminal development is necessary, if Americans are to meet on a National scale the obligations imposed by an expanding commerce.

Let us now examine a typical large port terminal.* This port includes half a dozen competing railroad-terminal services, all interlocking as a result of previous development through 20 or 30 years of intense competition. Some of the terminals must actually be losing money in the effort, but they must keep going to secure their share of the traffic. This port city has grown solidly around the railroad terminals and the water-front district, enclosing them and restricting the possibility of their proper development.

Of the total car movement, only one-sixth is through land interchange, as compared with more than one-half in Chicago, that is, traffic having no business in the city proper. More than two-thirds of the total car traffic is interchanged between the roads, and two-thirds of this is done on the congested water-front, while only one-fourth of that car movement is direct export and import movement. In other words, city business and marine business is hopelessly interlocked in the attempt to carry on both in the same location. This emphasizes an important premise—that the water-front is not the place for city business, nor is it the place for rail clearing or storage operations.

Now, the peak load of this port is quite severe. The terminal handles 25% more cars loaded and empty during the peak load than during the normal month. It handles 50% more cars received immediately after harvest time, and, at times, the grain receipts are several times larger than the average for the month. The result is that cars pile up in the terminals by the thousands. The seasonal excess (over minimum) may be as much as 15% of the total car receipts, and months are required to eliminate this excess car holding.

This emphasizes the fact that the clearing capacity of terminals depends much on their mobile reservoir capacity—the "liquid assets" of the operating man. That point has indeed been emphasized in this discussion, but it means capacity of warehouses as well as of railroads. The railroads should not be required to provide all the warehouse capacity—a bad practice which greatly decreases the effective utility of railroad facilities.

Railroading is a continuous function; shipping is an intermittent one. The difference in the turn-around time in boats and cars must be met by reservoir capacity. Who is going to provide that capacity? That is one of the great problems of the port plan. If it is not provided, every harvest time will result in a vast car movement to the seaboard, the clogging of terminals, and a serious shortage of merchandise cars in the interior. The coal problem is similar. One 10 000-ton cargo would require 3 miles of cars standing, 2 000 or 3 000 truck loads, or 8 miles of trucks in line. Imagine the activity required in a port terminal designed to handle 20 cargo ships at a time, with an average of 5 days turn-around (which should be possible

* Based on a detailed technical survey of origin destination.

instead of 10, 15, or 20 days' turning time). What is needed at present is more movement, not more cars or ships. It is the cost of idleness that eats up the profits.

Summarizing this very brief discussion, commerce is interested in:

First.—The clearing capacity of the gateways during heavy traffic seasons. This is analogous to the problem of designing a power plant to carry a peak load.

Second.—The over-all cost of transportation from the producer to the consumer, including the important terminal cost. It is the total cost from arriving train to departing ship that controls.

Third.—The time consumed in transit, avoiding expensive and embarrassing delays.

Fourth.—Economic routes overseas which provide least time and least cost.

Fifth.—The provision for continuous development to meet future growth of traffic. In this respect, the newer ports—the younger ports—have a great advantage, because they are not handicapped by expensive precedent.

Sixth.—More consideration of the transport machinery back of the bulkhead, that is, rail, belt lines, and motor transport auxiliaries, are required in the port, as well as the water-side facilities and equipment, likewise so important.

Seventh.—The separation of city and water-side freight transport facilities is necessary to permit each to function without interference. This should be a major feature of the city plan.

Eighth.—Acceleration of carrier equipment. This may determine the success or failure of a port.

Permanency or supremacy cannot be guaranteed to any gateway, for, ultimately, Commerce will adjust itself and select its own trade routes and outlets, based on true economic stability.

LACK OF CO-ORDINATION IN DESIGN OF AMERICAN PORTS

By John Meigs,* M. Am. Soc. C. E.

Recently, a conspicuous official of one of the major ports of the United States, in an unfortunate moment of mental aberration, charged the Engineering Profession with responsibility for the lamentable fact that "this country to-day is secondary in importance to Great Britain and other European nations as a maritime power."

This ingenuous and surprising allegation was followed by the further count in the damning indictment that these hyper-technical malefactors—that is, engineers—or, as he neatly expressed it, "impractical and technical men," were animated by motives "sometimes prompted by selfishness, frequently by favoritism, and often by inexperience."

These initial strictures were then amplified by further charges of high professional crimes and misdemeanors on the part of various specific members of this Society, who had the temerity to design harbor structures not in accordance with his own secretarial views—this having been his vocation prior to his present incumbency of a responsible executive post.

If this highly placed official had additionally charged the impractical theorists of this Profession with the responsibility for the World War, for the present financial depression, and the unusual prevalence of mosquitoes on the Jersey coast, the sweeping indictment would have been complete, his animadversions would have been quite as just and logical, and no doubt it would have relieved his mind of the profound depression in which it was then apparently inextricably bogged.

Of course, such unmitigated absurdities as these would warrant no attention, save that they came from an incumbent of a prominent municipal-political office, and that they indirectly "point a moral and adorn a tale."

If, however, engineers reject this kindly meant solution of the problem of "what ails our American ports?", in fairness they presumably must suggest a better one. The uncontrovertible fact is, not that engineers have by their iniquitous dominance been responsible for the comparative backwardness of American port cities, but, on the contrary, that they have had far too little to do with their development, having been in most instances, until very recent years, notable in important port councils mainly by their absence.

It is true that the services of engineers have long been utilized in port design along the more technical lines of harbor planning and in the detailing of various port structures, but, in the larger aspects of the art, the general design and co-ordination of port layouts, they, unfortunately, have not been able to make their influence felt as they should.

Too frequent changes of political administration in the greater number of the ports have made impossible the adoption and carrying out of logical and comprehensive plans, however good the intentions of their proponents may have been, have rendered futile the well meant efforts of engineer subordinates to institute well considered programmes of development, and have resulted

* Cons. Engr., Philadelphia, Pa.

in piecemeal and inconsistent efforts at isolated betterments. Each successive, short-lived administration has entered into office as a rule suspicious of the plans and procedure of its predecessor, anxious to make an ornate showing for itself, and regardless of the troubles left by it in the hands of its successor.

To illustrate this precession of American port luminaries, the speaker may mention the fact that nearly ten years ago, when the American Association of Port Authorities was first organized, as a humble member thereof he became acquainted with practically all its membership, including the representatives of the ports of the United States and Canada. During this decade, the speaker has seen in the case of the ports of the United States at least three changes of administrative officers and, in some instances, four or five; while in the case of Canadian ports they have remained for the most part in the hands of the same executives for this entire period—men trained, salted, and seasoned by long and valuable practical experience. Not one of the municipal port officials of the United States then in office is now connected with port administration.

This applies, it is true, mainly to the chief executives of these various departments, but it affects also the working personnel to a considerable extent and makes impossible the proper carrying out of consecutive programmes of improvement.

The better balanced developments exhibited to Americans by European and by some Canadian cities—notably, Montreal—and the superior economies of operation possible thereby, are due in large measure to their rational conception of the proper function of a port administration as a genuine business organization rather than a political or social diversion.

When referring to comprehensive port developments, the speaker does not necessarily mean the somewhat flamboyant and spread-eagle projects designed to provide for the hypothetical needs of unborn generations of men and unbuilt navies of ships with which the port fathers have amused themselves in so many recent instances, admirable in themselves though these plans have often been. Rather, he more especially wishes to emphasize the necessity for proper balance in port layouts, be they large or small in size, and an economic co-ordination of the various parts and functions of the port.

Provisions for the receipt and transfer of freight to and from land and marine carriers are essential, of course, but of equal importance must be considered the provision of facilities for its warehousing and merchandising. The complete port consists not only of its channels, anchorages, piers, quays, and transit sheds, but also of proper rail and road transportation facilities, and, not least, ample provisions, both outdoors and under cover, for the short and long-time assembly of cargo and the protracted storage of it in warehouses for eventual reshipment, for resale at favorable opportunities, for repacking, assembling, manufacturing, or other preparation of it for the market.

Have American municipalities devoted the proper study to this important subject as a scientific problem, or are the ports being permitted just to grow, "Topsylike", along the lines of least resistance? To any one familiar with the

trend of port development in the United States, it is not necessary to answer this question. He will know only too well that we are merely drifting.

Much money is being spent in the improvement of the harbors—tremendous expenditures in the aggregate are being made—but how much of this spending is wise and how much of it unwise, or even profligate, is a serious question. When two ports of approximately equal commercial movement are found, one with nearly twice the wharf space of the other and still feverishly engaged in spending on more, and more, and more wharves, it looks as if satisfactory explanations of the "whyness" of this spending would interest the citizen taxpayers who are providing the funds for the possibly misguided expenditures.

When port officials devote their energies solely to constructing spectacular new piers, and entirely neglect the equally important railroad and warehousing facilities to back them up efficiently, and the proper improved mechanical equipment to facilitate the despatch of cargo, it is time for a halt until the entire system of port administration can be placed on a genuine business basis.

Permanent boards, composed of business executives, operating men, and trained engineers, should be placed in charge of these matters, paid decent compensations, and permitted and required to stay on the job. Then and then only—when the ports are administered as business enterprises and not as political opportunities—can Americans hope to compete in operating efficiency with well organized overseas competitors.

No such reckless and extravagant use of water frontage is observable anywhere in the world as in the harbors of the United States, which, provided by Nature with facilities almost ideal as compared with the great ports of Northern Europe, have been developed in truly frontier fashion, sprawled out over many times the length and area of other world ports of corresponding commercial importance, and operated with consequent inefficiency.

Per foot of steamer berthing space, American ports show an annual unloading capacity of from one-third to as little as one-tenth that of well planned and properly administered foreign harbors. When one considers what this means in decreased costs of every kind—both in connection with construction and operation—the greater administrative facility, and the more efficient management in every particular, the facts in the case demand most serious attention.

As a typical American example, the municipality of Philadelphia, Pa., has about 15 000 ft. of highly improved, deep-water, wharf frontage or berthing space publicly owned, 65 000 ft. of additional deep-water berths under private control, and, approximately, 50 000 ft. of additional berthing space suitable for coastwise and river-trade purposes, a total of nearly 130 000 ft. of improved wharf frontage. Not a square foot of warehouse space in the port is municipally controlled, and, compared with foreign ports, there is relatively little under private ownership. The warehousing is done largely on the pier sheds, where it was never intended to be—and should not be—permitted; and no effort whatever is made to utilize the port equipment intensively.

Abroad, the Port of Manchester, England, handling but slightly less foreign business than Philadelphia, possesses only 34 000 lin. ft. of berthing space, less than one-half of the deep-water berthage in Philadelphia and about one-quarter of the latter's total berthage; but, on the other hand, Manchester has warehousing accommodations amounting to approximately 3 200 000 sq. ft. as against Philadelphia's inadequate quota of 1 200 000 sq. ft. In addition, the Manchester docks are equipped with most elaborate mechanical handling equipment designed to facilitate cargo loading and unloading and to make every linear foot of frontage of maximum cargo capacity.

A little nearer home, in Canada, the Port of Montreal manages somehow to handle an annual foreign tonnage of nearly the size and importance of Philadelphia's deep-water berthing accommodations—and accomplishes this in an open navigation season of less than 8 months, or only two-thirds of Philadelphia's working year.

The case of Philadelphia is not mentioned as unique. It is merely typical of current American practice along these lines, and nearly all the other ports of the United States are justly subject to the same criticism.

Are these inconsistencies of performance to be accounted for by any radical differences in classes of cargo handled, or the industrial surroundings of these several ports? Most probably they are not; and, also, most certainly the current practice on one side of the line or the other is wrong. Are the ports of Manchester and Montreal handling more tonnage per linear foot of available berthing space than they properly should and, at the same time, show a decent and kindly regard for American sensibilities; or, possibly, has Philadelphia and her sister ports more piers and berths than they have any legitimate need for, and which they have not yet learned to use properly?

If, however, the municipal authorities have shown lack of forethought in the study of these matters, private terminal managements cannot be accused of like carelessness, as some excellent examples of well balanced design are exhibited in their plants.

In the Bush Terminal, in Brooklyn, N. Y., for instance, with a total berthing space of approximately 16 000 lin. ft. and a pier area of more than 1 000 000 sq. ft., the warehouse area is in excess of 2 000 000 sq. ft. This terminal presents an exceedingly interesting study, in that although it is by no means a model from a construction point of view, it may be assumed to be an almost ideal layout from the standpoint of the balancing and proportioning of its various facilities in their relation to each other and to the general plan.

The present layout being the result of a gradual growth of several decades, from an insignificant beginning, its various piers, warehouses, railroad, and other facilities have been constructed one unit at a time during successive years in response to the actual demands of the business of the terminal, and, in its present state of completion, it may be fairly considered to be planned almost exactly to meet the accurately determined needs of this particular location. This great commercial terminal is commended to city fathers for their careful study.

Decided progress was made during the World War in scientific designing in the case of some, but not all, of the Government terminals constructed for

the shipment of munitions, and these steps in advance might well be emulated by municipal port planners.

In the great South Brooklyn Army Supply Base, a most radical departure in terminal proportioning was made when, in order to balance 7 800 lin. ft. of berthing space and 585 000 sq. ft. of pier area, there was provided more than 4 500 000 sq. ft. of warehouse floor area. This proportion of warehouse space to pier area of more than 7 to 1 may be far in excess of the correct balancing of these facilities in the average commercial terminal. This, however, is a preferable fault to the contrary one of insufficient warehouse space and a superfluity of piers.

It is poor business to build piers at from $5 to $10 per sq. ft. of deck area, and permit them to be used as storage warehouses, while the latter class of structures can be provided at from one-quarter to one-half the cost of pier area.

When comparatively cheap warehouses and inexpensive mechanical handling equipment will enable the expeditious clearing of the decks of expensive piers and permit of doubling, or trebling, the number of vessels capable of being accommodated at their berths, there would seem to be considerable virtue in a policy of port development calling for liberal warehousing provisions and the installation of ample cargo-handling machinery.

Is it not time that American municipal port executives ceased specializing in piers, and piers alone, and commenced an active campaign of providing other port facilities in proper relationship to their wharves?

Most of the seaboard cities of the United States need improved intra-harbor rail facilities, effective belt-line railroads, up-to-date mechanical equipment, and extensive increases in warehousing space incomparably more than a far-flung series of individual piers practically unrelated to each other and the general port plan.

It has been argued that railroad and warehouse installations are not proper objects for the expenditure of public moneys, that it is all right to build piers, but all wrong to provide the co-ordinate facilities which will make the piers of maximum use to the community. This is the most egregious stupidity.

Who can say where the proper functions of the municipality stop and those of private capital begin? The propriety of such expenditures can be determined only by the extent and urgency of the existing needs of the community, by the exigencies of each actual case.

The speaker is no advocate of undue paternalism in government, and he thoroughly believes that private capital should be encouraged and assisted in all legitimate lines of investment. Private management is nearly always superior to that by governments—be they municipal, State, or Federal—in point of economy, efficiency, and almost every vital factor of operation. If private money will provide all the port facilities, docks, railroads, warehouses, and what not, let it do it by all means—under proper public supervision of the general plan of these expenditures—but whenever private capital fails to take advantage of its opportunities to be of public service, then the public itself must take hold and provide rationally for its own needs.

In his discussion, Mr. Long* has already given some illuminating data on the subject of warehousing principles, and the figures previously quoted are merely random examples selected to suggest the possibilities in this line of investigation. The subject is certainly worthy of more careful study than has yet been given it, and the results in the way of improved port economics to be reasonably expected from a careful and conscientious investigation of the entire subject, and a practical application of the vital facts thus discovered, would amply justify its costs.

Let the municipal authorities wake up; let them show a little ordinary business sense; let them give their engineers and shipping experts a chance to work out their port problems along scientific lines—that is, in accordance with the dictates of sublimated common sense—and the United States will no longer remain as the before-quoted distinguished critic has stated, of "secondary importance to Great Britain and other European countries in maritime trade", at least, in so far as the proper economical and expeditious handling of maritime commerce at the water-gates is concerned.

* See p. 164.

A BRIEF COMPARISON OF AMERICAN AND FOREIGN SEAPORTS

By W. Watters Pagon,* M. Am. Soc. C. E.

To persons content with superficial observation, the most striking fact about the two groups of ports—European and American—is their marked dissimilarity. Yet when a more intimate study is made, one finds, of course, that much the same factors are operative, and the differences that have developed on the opposite shores of the Atlantic are no more marked in their real essence than the differences in manners and language between the British Isles and America.

The fundamental difference is largely topographical. The speaker cannot recall an American seaport of consequence where he was not asked the question, "Do you not think that this is a wonderful natural harbor?" and, doubtless, it was, for most American seaports are natural harbors. A port, however, is more than a harbor, and depends for existence and prosperity on commercial and political geography and on the business acumen of its traders. Because of this many of the European ports are located on rivers, far from the coast, and their harbors have largely been dug, piecemeal, from the land as additional space was needed. It would be quite accurate to say that European ports have natural wharves and artificial basins, whereas American ports have artificial wharves and natural basins. The obvious consequence of this—somewhat accentuated in America by the individualism of the pioneer and the temporary character of his construction—has been to foster the building of docks in Europe and of piers in America.

On first thought this distinction is all important, yet the speaker cannot but feel that it is of little importance. A quay wharf is nothing more nor less than half a pier, and whether the wharf is a masonry bulkhead retaining an earth-fill, or a piled construction, can only affect the economy of doing business, through its influence on capital and maintenance charges. In fact, though Liverpool is typically European in its materials of construction, it is quite similar to American ports in its layout, and other foreign ports have layouts containing piers—even piers of American pile construction.

Just why tideless docks have been used so extensively in all ports of Europe in recent years is not entirely clear. In Antwerp, for instance, the earlier construction was on the principle of the marginal wharf, very much like that at New Orleans, La. In London, there is a theory that the earlier basins were built quite largely because they provided a water area that could be fenced in to protect shipping from pilferage; which theory is supported by the inscription on the West India Docks, dated 1802, namely, "* * * this Range of Buildings Constructed together with the Adjacent Docks, * * * for the Distinct Purpose of Complete Security and Ample Accommodation (Hitherto not Afforded) to the Shipping and Produce of the West Indies at this Port * * *". Hamburg and Copenhagen have used the idea of docks, without gates, because it lends itself to the requirements of their "free

* Cons. Engr., Baltimore, Md.

ports". Rotterdam has real need for large basins—even if no quays were provided—because a large volume of its business consists in transshipment from Rhine and canal barges directly to vessels that are moored to pile dolphins and buoys in the docks. Yet, of course, there are many advantages to be gained by tideless docks in such a port as London, where the tidal range is 25 ft. and the tidal currents are strong.

Therefore, it cannot be said that the common American type is better in general than the European type, or that it should always be followed in the United States. The better principle to lay down is that both types have their advantages, and American ports should develop their newer port works along either line, according as the local requirements favor the one or the other. To follow the American plan exclusively is to blind oneself to the possible economies of the other, a fact which has been appreciated by some of the port authorities, and certainly it is contrary to the ideal of the terminal engineer, which is to build so as to gain for the owner the maximum ultimate economy.

For the purpose, therefore, of understanding the other factors that influence the type of development, let us set aside the factor of tidal range—a fundamental one to be sure, yet one that is purely local to every port.

Next in order of discussion is, then, the matter of relative permanence of construction. On this subject many elements have a bearing, for example, relative age of ports, tides, and other physical elements, seat of ownership, density of business, etc.

Relative age of ports will be discussed more fully subsequently, but those foreign ports the age of which is so great that their business activities are well established, can well afford more permanent structures than the recent ports in this country. Yet, this consideration did not cause Manchester to build cheaply, although its port is an infant, even when compared with the Atlantic ports of the United States, and when Antwerp was opened to trade again by Napoleon, the structures built were of permanent type. Railroad-owned Southampton is also an exception; so probably this reason does not generally obtain.

Such influences as tides may have a considerable bearing on construction where structures are in the tidal range, but they would have no bearing within the docks where the water level is almost constant. In the United States the range of tide is not a determining factor, because the American type of piers may be found at Baltimore, Md., with a tidal range of 1 ft., and at Boston, Mass., with a range of 13 ft.

The questions of seat of ownership and density of traffic are closely related. Of course, the tendency in all countries is to build public works of permanent materials, and this may have considerable bearing in those ports where city or State or other public authority controls the works. Manchester and Southampton, however, are privately owned, and here permanent construction is also found; and the privately operated "free ports" are of similar nature. Even in ports which follow the leasing system, where the lessee's wishes govern largely, there is no marked difference. Therefore, it is probable that the mere fact of ownership has no direct bearing, to the exclusion of other factors.

On the other hand, delegation of ownership or control of a preponderant portion of a port to a single body—whether public, semi-public, or private—is conducive to concentration of the business over the minimum of space. Density of traffic also goes hand in hand with permanence of construction. Thus, a line of "jitneys" may amply provide for light, suburban, street traffic, but subways are the only solution for heavy metropolitan service, and heavy capital expenditure may be economically justified under the latter conditions.

This is, the speaker believes, the most important factor, and a little detailed study will emphasize the point. It has been stated that certain European ports handle ten times as great a tonnage per linear foot of quay as certain American ports. Assuming that cost of construction of berthing space alone in the two countries is in the ratio of 3 to 1, then it follows that those foreign ports are doing an amount of business certainly three times as great per dollar of capital investment. If only this much is true, it certainly does not speak well for the American extensive system when compared with their intensive system. There are also, however, many other correlated gains which follow from intensive development. There is a further saving in terminal investment and operating costs by reduction in railway trackage and facilities; a similar saving in warehouses and transit sheds; a saving through the changed conditions which justify labor-saving machinery by permitting its constant use; a saving in truck mileage to outlying terminals; a saving of water-front mileage and, therefore, a reduction in value, thus permitting more widespread use of the shores for industrial plants the materials of which are water-borne.

By comparison, the most potent element of weakness in the ports of the United States is the decentralization of a pioneer country. Such a condition as that found in one American port, where only 1% of the harbor frontage is owned by the public, would be impossible in Europe, where the ports are highly centralized, for administration as well as for physical layout. London has its Port Authority controlling nearly all the important quayage. In Copenhagen, 58% of the quayage is controlled by the Harbor Authority, and 70% if city and State are included. Liverpool and Manchester are almost entirely in the control of the local authority, and the ports of the Low Countries are similarly held.

New Orleans, La., and San Francisco, Cal., are on a parity with these ports, and they are indicative of the success of the idea in America. In San Francisco, the Authority has consistently striven to increase the density of traffic by yearly comparisons of the tonnage handled per square foot of pier. The space allocated to a shipper is contingent on the intensity of use shown previously. The Authority at New Orleans reserves the right to place vessels at wharves which are not in use, even though they are allocated on yearly leases.

In marked contrast with the natural facilities offered by American harbors are some of the development difficulties to be observed in European harbors. The extreme range of tide has been mentioned, with its attendant system of locks and dikes. Contrasting with this is the situation at Copenhagen where the tidal range is slight, but where the tidal currents are so strong that a dike 7 300 ft. long has been built across the Sound, with locks for vessels

and sluice-gates to control the currents. The newer portion of the harbor has been reclaimed from the water and enclosed by about a mile of breakwater. Amsterdam for more than a century had difficulty with the depth of water through the Zuider Zee, and has built two canals to the North Sea—one of which was not successful—to maintain its position. The later one is second only to the Panama Canal in section, and was built at a cost of about $25 000 000. Rotterdam, located more directly at the mouths of the Rhine, has had to face the same problem of maintaining its channel depth to the sea, and has expended only slightly less than its neighbor. Probably the most courageous of all is Manchester, which, aspiring to become a seaport, spent nearly $90 000 000 on a ship canal, and now is almost on a par with its former port—Liverpool. In some ports, the State has assisted the city, but the greater the proportion expended for aids to navigation the less there was available for quays, sheds, warehouses, etc., and, therefore, the greater the need for increased density of traffic.

One weighty difference between the continents lies in the fact that American tonnage is predominantly for export, whereas, in many European ports, it is for import or for transshipment. This is notably true of the grain trade. However, Amsterdam and London, for instance, have extensive warehouse facilities for goods awaiting re-export, which largely overshadow the other port facilities. Much of the wealth of these European countries has been derived from such storage of goods awaiting a favorable market, in addition to the profits accruing to the local ship-owners from transport of the cargo.

The "free port" is peculiar to Northern Europe, where it has been fruitful. Developed to meet a local situation, it has spread to foreign countries. From the traffic standpoint, it is much the same as an interurban railway terminal, where the dense mass of passengers from subway or elevated railway are distributed to the radiating lines which end there, or *vice versa*. From the economic standpoint, it is a wedge, a re-entrant salient, in the customs frontier of a country, which extends the commercial freedom of the seas to include a safe harbor where goods may be safely transferred, blended, manufactured, or stored, awaiting continuance of the journey to other countries. It is a "bay" connected with the free ocean and enclosed on three sides by the customs, whereas a bonded warehouse is an economic "island" surrounded on all sides by customs.

Because of its nature, a free port is, in general, owned by the State or Harbor Authority and leased to a private lessee. When the Government of the United States adopts the principle of the free port, which now seems entirely possible, it will have at New York, Baltimore, Norfolk, and other ports, a series of Ordnance General Supply Depots with berthage, railways, storage, fencing, and all other adjuncts of a free port at hand ready for lease. At least one of these ports can easily be developed to equal the present size of the free port at Copenhagen. For equal success, however, there must be aggressive commercial activity to provide the business.

In spite of superficial differences, therefore, there are few factors of importance which are not operative on both continents. Of course, most Euro-

pean ports have much the advantage in point of age, for Tacitus writing in A. D. 61 mentions London as having "a number of merchants and trading vessels", and several Continental ports antedate the Norman conquest. Yet the rise and fall of ports has been rapid, and whereas Antwerp had become one of the foremost ports of the world in the years from 1500 to 1560, she had declined to almost nothing at the end of the century, owing to civil wars and political dominance of other States. Thus, age can create only an historical background, which may facilitate the inauguration of some new venture, but lack of age has been no deterrent to new ports where the local spirit was aggressive and conditions were ripe.

Whether conditions are ripe for American seaports no one can predict. It hinges quite largely on the continuance of the merchant marine. No European city has become great through the activities of its non-citizens, but through those of its own people, who owned their ships and brought the goods to storage under their own house roof or warehouse. The profits from vessel and cargo went to support the Rubens, the Michael Angelos, the engineers, and other professional men, as they will in the United States—if the merchant marine is made to flourish—to those ports the citizens of which own and operate their vessels and lines.

SOME OBSERVATIONS ON PORT FINANCES

By Edwin J. Clapp,* Esq.

The speaker is not going to discuss the subject of an ideal method of collecting port revenues, nor consider, except briefly, the various expedients now practiced in raising enough money to operate port facilities. He is going to discuss, primarily, the practical financial difficulties that confront public port construction work in the North and South Atlantic outports, because of the established practice of the railroads in offering free berths to steamships in the foreign trade. All the Atlantic ports of the United States, except New York, are called outports.

Briefly stated, the situation is as follows: Each railroad at its chief port, often at several of them, maintains a complete set of oversea terminals, consisting of water-front yard with switching equipment, open and covered piers or wharves, grain elevators, cranes, and other machinery for handling bulk freight. Generally speaking, it maintains and operates this ocean terminal as part of the railroad system, just like the team tracks and freight houses of its land terminals. Rail rates cover not only the cost of transportation, but the often greater cost of maintaining and operating the terminals. No charge is levied on the motor truck which backs up to a freight house to deliver or receive freight. No charge is levied on a steamship that backs up to a pier to deliver or receive freight. The interest, depreciation, maintenance, and operating costs of the pier are covered by the rail revenues earned on goods hauled to and from the ship.

The outports, intent on increasing the volume of traffic flowing through them and the number and frequency of their overseas services, have found marked disadvantages in this system of railroad ownership of pier facilities. The railroad, having invested heavily in a terminal, tries to monopolize all competitive traffic that passes over it; that is, all traffic to and from points reached by the railroad pier owner or its connections—and this includes practically all the traffic the steamship carries except local port business. Other railroads are kept from interchanging traffic with the steamers when the pier owner refuses to switch their cars, or levies on these cars such a heavy switching charge that the other roads are discouraged from carrying traffic the revenue of which is thus diminished. In either case, the steamship line tends to find itself confined to the service of the carrying power and the soliciting force of one railroad, instead of all the lines centering at the port.

Likewise, the railroad pier owner generally bars or restricts the use of its pier for the accumulation of local cargo delivered by teams, lighters, or the short-distance motor-truck common carriers. This is business on which the railroad gets no revenue. Such traffic occupies pier space which railroad revenue freight might use. It is good business for the railroad, but bad business for the ports the traffic of which would expand if all piers were freely open to all inland carriers by rail, highway, or water. The railroad, however,

* New York City.

handling all of 500 000 tons of freight moved through its ocean terminal, can make more money than by handling one-half of 800 000 tons. At least, so the railroad officials have calculated.

An efficient port is a funnel through which are poured the exports and imports of a wide hinterland. Railroad ownership of ocean terminals has interfered with the freedom of that flow in the outports. The outports see their disadvantage when they compare themselves with publicly owned ports like Montreal, Que., Canada, and New Orleans, La., where the berths for steamers are owned by the Dock Board and the facilities are connected with each railroad by a public belt line. Each steamer is thus cut off from exclusive connection with any rail carriers. For a moderate, uniform switching charge, covering only operating cost, the belt line switches cars between any berth and any carrier. Every steamship line has every rail carrier working to create traffic for it, and all on equal terms. In New York, steamers do not dock at the railroad piers, but across the harbor at piers in Manhattan, Brooklyn, or Staten Island. Railroads deliver freight to the steamers by lighterage. The intervening water serves as a belt line to cut all the water carriers from all the land carriers.

An outport sees that public piers are preferable to railroad piers from a traffic standpoint. Moreover, the outport sees the publicly owned ports going ahead with great extensions, such as have been completed or are in process at New York, Montreal, and New Orleans. In general, it can be said that in the provision of new facilities, the outports have stood still; the railroads are building no new piers and have built none for years. This is partly because the export and import business has declined from a major to a minor element in the traffic on the railroads, and the railroads have not the money to build to meet the less important needs. The insistent demand for money to rehabilitate the road and equipment of carriers, and to expand local terminals for domestic traffic, will absorb for years all the funds the railroads can raise, and there will be nothing left to spend on ocean terminals.

Thus, not only is it better policy for the city or the State to supply piers for oversea carriers, but it is the only way in which port development can proceed. However, if an outport erects a pier, or a group of piers, it finds it difficult to make the steamships pay anything for their use, because a few blocks away the railroads offer their piers rent free. The railroads recoup themselves by their rail earnings. The city has no direct earnings out of which to pay the cost of carrying and supplying piers free to steamship users. Few cities are financially able to carry this annual loss for the sake of the general advantages which port development brings to commerce and industry. How are the outports to finance their new public piers, meet the cost of their interest, maintenance, depreciation and supervision, or operation? There are four ways in which this money can be raised.

First.—The piers can be supplied free and the annual cost taken out of the city taxpayers. This is not practicable. Indeed, it has become customary for the voters or their representatives to authorize port expenditures only on condition that they are to be self-supporting.

Second.—The annual cost of a pier can be met by a dockage charge, levied against the ship each time it uses the pier and proportioned to the size of the

vessel and the length of its stay. This is a main source of revenue at New Orleans, where it is supplemented by a "sheddage" charge levied on the ship for the use of covered space, and by an annual "preferential assignment" charge per square foot of space paid by the steamship line for a semblance of permanency in its berth. In some other ports, these charges against the ship are commuted into an annual rental, as at New York, where the pier is turned over to the steamship line for its exclusive use.

Third.—The annual cost of a pier may be met by the imposition of a "wharfage" charge levied on the goods that pass over it. These revenues may be supplemented by storage charges levied on the goods which do not simply pass over the pier, but remain there for a time. This method of financing piers, developed by the railroads, is practiced at the South Atlantic ports. They have long collected charges according to a "wharfage, storage and handling" tariff, the charges being added to the rail rate on southeastern export and import traffic. For years these charges have been far too low to meet the cost of maintaining and operating the piers. Since January, 1921, a new tariff has carried charges designed to be adequate.

At some ports such wharfage charges are not added to the rail rate, but paid by the railroads out of the rates. This is done at Montreal. Its chief source of revenue is wharfage, most of which is paid by the railroads out of their earnings. Montreal has a very scientific system of raising its revenues. The wharfage charges already described are kept high enough to provide interest on the piers. The berths are then leased to steamship companies at rentals sufficient to carry the annual cost of the sheds. Elevation and storage charges make the grain elevators of the Montreal Harbor Commission self-supporting. Switching charges paid out of rail rates to the harbor belt line are designed to make the belt line carry itself. At Galveston, Tex., a similar method prevails. The ocean terminal facilities are owned by the Galveston Wharf Company. Its revenues come mainly from wharfage on goods allowed by the railroads out of their rates, and dockage on ships, paid by vessels according to their size and duration of stay.

Fourth.—The entire cost of maintaining and even operating piers may be met out of railroad revenues, as is the case with the railroad-owned piers at the outports.

As it is not practicable to propose that publicly owned piers at the outports shall be maintained at the expense of taxpayers, the only way to finance them has been by the dockage or rental method and by the wharfage method.

To rent public piers on a self-supporting basis will long be a matter of great difficulty at the outports. The speaker is not unmindful of the experience of Philadelphia, Pa., a railroad port which, ten years ago, bravely "took the bull by the horns", built public piers, and rented them for what they would bring, alongside railroad piers offered free. For many years the rentals were almost imperceptible. To-day, some of the newer berths rent on a basis to carry them, but the net income of the Dock Department, after taking out administration and maintenance expenses, is an insignificant return on the $12 000 000 expended thus far. Philadelphia frankly set out to carry its piers, like its highways, at public expense. No other outport can afford to imitate her.

In the speaker's opinion, it would be a mistake for an outport suddenly to attempt to finance piers on the basis of rentals or dockage collected from ship lines, even if this method were practicable. Everything tends to gravitate to New York. Free berths at the outports have been an inducement to more than one steamship line to establish there. When the railroads were built from the seaboard into the Middle West, the Erie Canal had already concentrated the exportation of grain and grain products at New York. The new railroads terminating elsewhere set out to induce the flow of this traffic through their ports also. They offered the steamships free berths and they also offered larger earnings than obtain at New York—larger steamship earnings because of the "differential" rates (lower than those which then applied to New York), which the railroads terminating at the outports were willing to accept. The outports have fought the abolition of the differentials. They should go slow in abolishing free dockage. Examination of export and import figures proves that the drift to New York is not growing weaker, but stronger. Such new lines as the outports get are generally the result of small beginnings. A free berth is a constant inducement to such experiments.

Financing new public piers at the outports by means of wharfage levied on the goods presents no complications at the South Atlantic ports where the rail carriers already levy wharfage and handling and storage charges, in addition to the rail rates. When new public piers are built, the rail rate will set the car on the city pier. Then the city can levy the regular tariff, handling, wharfage, and storage charges. These are designed to be sufficient to carry the old railroad piers which suffer under very heavy maintenance costs. The tariff charges, therefore, should more than carry new modern city piers.

At the North Atlantic outports, financing public piers by wharfage charges will not be so simple, because these charges cannot be added to the rail rate. As explained, the rail rate to a North Atlantic port includes delivery alongside the ship. The railroad, without additional charge, unloads the car and charges no wharfage on its contents. At a city pier, the railroad would deliver and unload the car. If the city tried to charge wharfage on the contents, this charge, added to the rail rate, would throw the cost of shipping *via* this pier "out of line", compared with the adjacent railroad piers. That is, at North Atlantic ports, if wharfage is to be collected at city piers, it must be collected not from the shipper in addition to the rail rate, but from the railroad out of the rail rate. This would be no new practice for the railroads. Already out of their rail rates they pay a wharfage sufficient to cover the overhead and the operating cost of their piers; they pay this wharfage to their own terminal units. Why not pay it to a new independent terminal unit which relieves them of the terminal service? Then the railroad would have the same net revenue for its haul whether the shipment passed over its pier or the city pier; in either case, it would retain the rail rate less a terminal deduction for wharfage. Such rail-rate terminal allowances made to city terminals by the carriers would make city terminals self-supporting. This would make it simple to obtain public funds to any desirable amount.

In other words, this is the situation: In the North Atlantic outports, ocean terminal facilities have been supplied by the railroads the rail earnings of which include a quota to pay for the upkeep of these terminals. Expanding commerce, larger ships, the advance of the engineering art, all require new and improved facilities. The railroads are financially unable to supply them. They can be supplied out of public funds, if the railroads will make to the new terminals the same terminal allowance they would make to their old terminals. Of course, the carriers would be glad to have the outports build piers and make no terminal allowance at all. They make no terminal allowance to the city piers at Philadelphia. On traffic which the railroads carry for movement over these piers, they retain the full rail rate, both that part collected for the haul and also that part collected for the terminal service, which includes supplying a pier. The cost of supplying the pier is thus thrown on the city, which shifts part of it to the steamship lines as rentals, but shifts most of it on the taxpayers.

To reduce the suggestion to concrete form: Suppose a North Atlantic outport builds a modern terminal unit, consisting of open and covered piers, a grain elevator with galleries to each steamship berth, a supporting warehouse, an adequate railroad yard, and a belt line cutting the main break-up yard of each rail carrier. Each rail carrier would pay the belt line an adequate switching charge for taking a car and setting it at its berth in the new terminal. This would supplant the service rendered by the railroad's switching engine in moving the car from the break-up yard to its own pier. The railroad car at the public terminal would then be unloaded by the railroad's own men sent there or, better, by the terminal's men, and the railroad would pay a proper handling charge for the service thus performed for it. Finally, the railroad would allow the terminal a per ton wharfage equal to the interest and maintenance cost of its own piers distributed over the tonnage handled there.

The railroads themselves would profit from such an arrangement. They would be supplied with new and additional facilities without cost, save as they got traffic to move over those facilities, and then the cost would be the same as that now assumed in the case of traffic moved over their own piers. At some of the outports, the carriers stand enormous losses by carrying cars of exports under load, because they have no adequate pier space to hold them. The initial wharfage allowance required of the railroads could be reduced in the course of time. The city's overhead on its terminal would be less than that of the railroads; the city could get its money for 5%; the railroads pay 6 per cent. The railroads pay 3% taxes; there would be none on city property. The overhead on the money invested would thus be 4% per annum less than if the railroads themselves built additional terminals. Maintenance at the new piers would be far less than at the old railroad structures.

The wharfage required of the railroads, in the course of time, could be further reduced as new sources of revenue arose for the new terminal. The larger steamship lines seeking it could be charged a "preferential assignment" for regular berths. Some of the lines would require special types of shed or equipment, but such lines could pay interest on the special facilities provided for them, a rental carrying the pier superstructure, as at Montreal. Adequate

tolls would be collected on freight carried to and from the piers by trucks and lighters. In all likelihood, the wharfage required of the railroads would be in time only a fraction of what their own piers now cost them in wharfage. It is not impossible that in time the new terminal would become quite self-supporting. It is a plan by which the railroads could gradually work out of the heavy terminal expense they now carry on export and import traffic.

The speaker realizes how sketchy this discussion has been; he knows the difficulties involved. The new terminal should be built and operated only by the highest type of public commission such as have been described by Mr. Cowie and Gen. Beach. The best commission or best authority is one representing the business interests which handle that transshipment which is the port's function. On this Port Authority, both railroads and steamship companies should have adequate representation. Of course, the new terminal units must be built gradually; the railroads should not be asked to help finance terminals which will simply empty those already in existence. There is no use in bedeviling the railroads; but for them there would be no outports; they developed them. The time has come when further development is beyond their financial powers, when ideas of the benefits of competition no longer extend to approval of separate railroad-owned ocean terminals. The speaker believes that the railroads will be found ready for co-operation in the manner herein outlined. If they were not ready, he believes that the Interstate Commerce Act, the Transportation Act, and the Merchant Marine Act, give the Interstate Commerce Commission power to compel such co-operation. Pending construction of public terminals, the main evils of the present railroad-owned piers can be eradicated by the introduction of reciprocal switching among them, the switching charge to include adequate wharfage for use of one carrier's pier by another.

What is here proposed is that the transition from railroad to public ownership of ocean terminal facilities in the North Atlantic outports proceed without abolition of the present railroad practice of allowing out of rail rates a wharfage sufficient to provide interest and maintenance on piers for overseas carriers. It is proposed that a city commission of port business men construct a single terminal unit, as part of a port plan, and that the rail carriers allow to this new terminal, out of rail rates, the same wharfage they now allow their own terminals. It is asserted that this initial wharfage paid by the railroads can soon be reduced, because of lower overhead and maintenance costs applying to the public terminal and because the terminal will develop revenue from "preferential assignment" leases and outright berth rentals, as well as from wharfage on traffic brought by motor trucks and lighters, which will have free access to the new piers.

Neither the outport nor its railroads can afford to see its port facilities stagnate. An attempt has herein been made to present a plan whereby these facilities can be fairly developed, to the advantage of both railroads and the port, without disturbance of existing rate or traffic conditions and with that proper observance of the local situation which must modify any attempt to attain ideal conditions.

IMPROVEMENT AND DEVELOPMENT OF PORTS

By Carroll R. Thompson,* M. Am. Soc. C. E.

In the improvement and development of ports there is no question of more vital importance than the powers that are vested in the body entrusted with the control and administration of port matters. The best laid plans for increasing efficiency will fail in their ultimate purpose unless the port control is such that the various unit facilities can be co-ordinated into a smooth working whole. A single port unit may be designed and built and be capable of operating with the utmost economy and dispatch, but unless the other units are coupled with it to produce the same efficiency, the whole operation of the port will be inefficient. The absolute regulation of each and every element entering into port problems must be controlled by a port body, which, in turn, must be established, organized, and maintained so that it can be administered exclusively as a business proposition.

The work of the engineer is dependent on this control. How can the engineers of a port commission build supporting warehouses to operate in conjunction with pier sheds, unless the commission has the authority to build warehouses? How can the rail facilities in a port be operated to their utmost efficiency unless the belt line is operated on a belt-line principle? What is more discouraging to a port official than to find one of the port's most modern and fully equipped general cargo piers on which a preferential is given to a particular railroad company's freight, or on which one railroad is permitted to run its cars to the exclusion of all others? When such a condition exists there is only one result: The railroad freight that is not permitted to be run on a pier must be rehandled at a distant point and transported to the ship either by lighter or truck. The belt-line principle of operating to allow any railroad carriers to enter on the tracks laid on any pier must actually be in force and be subject to the control of the port authorities, a control which can compel that principle to be enforced.

This is true with every other unit and element connected with the operation of a port. The regulation of privately owned water-front facilities also enters into this question of port control, particularly in some of the older ports. Sometimes attempts are made to utilize tide-water frontage for other than shipping purposes. Unquestionably, the primary interest of any community in its port lies in its shipping development, and, therefore, docks for ships are of the foremost consideration. Water-front structures for private storage purposes or other uses should not be permitted.

Recently, in Philadelphia, Pa., a decision was made denying the plea of a large corporation for a permit to extend a pier to the pierhead line where the dock or water space on each side of the pier was less than 70 ft. and the pier extension only 55 ft. wide. In addition, it was proposed to erect a superstructure covering the entire area of the pier without any provision whatever for an apron. The proposed structure was also of such character as to indicate clearly its intended use as that for storage and manufacturing, or a combina-

* Asst. Director, Dept. of Wharves, Docks and Ferries, Philadelphia, Pa.

tion of both, rather than for shipping or commercial purposes. The absence of any provision for cleats, bollards, or any other means by which a ship could be made fast, confirmed this belief. Furthermore, the company entered into an agreement with the adjoining property owner by which it agreed that it would not dock any craft of any kind or description along one side of the pier, all of which indicated to the Dock Department that such a structure was in violation of the laws now governing the port. There was involved in this application serious questions—the extension, for instance, of a pier of inadequate width and inadequate water space and the apparent desire on the part of the applicant to secure for manufacturing and storage purposes an area located on the recognized property of the Commonwealth of Pennsylvania.

The Director of the Department of Wharves, Docks, and Ferries, in denying the application, stated that he was alive to the importance of the industry in question to the Port of Philadelphia, and recognized that every facility should be afforded for its further development, and although he recognized the fact that this particular corporation was handicapped for storage room, he was also mindful of the responsibility resting on him as an agent of the State to dispense its bounty and felt that the time was opportune for calling a halt on attempts to secure by license the use of State property for private purposes. In this case, the State property referred to, is the bed of the river between the bulkhead and pierhead lines, on which structures for maritime purposes only can be built.

If sustained by the Courts, this decision will have a far-reaching effect in advancing the development and improvement of the Port of Philadelphia, in that, as pointed out in the opinion, the sanctioning of a non-maritime structure could not be otherwise construed than inimical to the development and best interests of the port.

Attention is called to this decision to show the importance of the control of a port authority over privately owned port facilities and also the fact that the port authority will be less handicapped in its improvement and development programme when it becomes the owner of the riparian rights along the entire shore line.

There are many such problems confronting harbor authorities in their efforts to improve and develop the facilities of a port and very often they are helpless to correct inefficiencies, due to the lack of authority to control all the elements that enter into questions of port government. In one American port, some of the laws regulating port matters were enacted more than a century ago and have not been modified in accordance with the advanced and changed methods of the shipping business.

To reap the full benefits of the improvements and developments that may be made to the harbors, or even properly to carry on successfully the actual construction work of improvement and development, the port authority must have the power that will enable it absolutely to control and regulate each and every element effecting the operation, directly or indirectly, of the port as a unit or a series of units. Its work must be separated absolutely from politics and handled exclusively as a business proposition and it must not be organized and established so that a periodical change of directing heads will

cause a periodical change of policy. Continuity of policy must be preserved. When a comprehensive plan of improvement and development is approved and adopted, the work should be carried on and not fail through lack of authority by the port body. When the port commissioners, or the authorities with whom the control of the port are intrusted, are given powers that will enable them to control or regulate every question concerning the functioning of a port as a whole, the improvement and development of that port will then be much simplified and the port engineer will be much less handicapped in solving his problem of how to produce efficient terminal facilities.

PORT PROBLEMS IN NEW YORK

By John A. Bensel,* Past-President, Am. Soc. C. E.

The subject under discussion has been announced as "National Port Problems". As far as the speaker knows there are no National ports in the United States and, therefore, there are no National port problems, unless problems of immigration or Custom House operation are considered. These are the only National operations in American ports, but as they are not of direct concern to engineers, it does not seem probable that they come under the subject.

On account of these facts, the speaker proposes to discuss some of the problems affecting the Port of New York, as he sees them.

The first question which naturally arises is, what are the problems that affect the Port of New York and thus endeavor to find how they can be solved, if they need solution. At this point, it would appear that one enters into a land of mystery, but the guides are numerous and so are the solutions.

It is quite evident that to many the most important problem in the Port of New York is how to get rid of the water. Many solutions of this problem have been proposed, but probably the one which has occurred to one engineer —of simply filling in one or two of the rivers and a portion of the Bay, all of which appear to be entirely superfluous—is the simplest and easiest to understand, and to him at least the problem is solved.

Other schemes to eliminate the water appear in two quite different forms, one of connecting the mainland of New Jersey with Manhattan Island by means of a gigantic bridge and the other of establishing an indefinite number of small-bore tunnels, built far below the street grade, on Manhattan Island.

The public must be somewhat confused by the solutions proposed, one of which would make a track yard on the most expensive real estate in the world and the other would deposit the freight destined for Manhattan at locations where it is difficult to conceive that it could reach the consignee. In neither of these proposals is an explanation given of the reason for them.

The Port of New York is apparently holding its position eminently well. It does more business than its ancient rivals, London and Liverpool, do in combination, and practically one-half the trade of the country goes through its gates. It is not shown that freight movement would be any cheaper, nor would it by any possibility be any more rapid, and the question naturally arises, "why bother?"

In this connection, nearly thirty-five years ago, certain eminent engineers reported on the problem of how to increase the commerce of the port, and arrived at the novel conclusion that a four-track surface railroad with a track connection to every pier was the solution. Had this joke been perpetrated, the water-front would have been rendered inaccessible and the capacity of the port curtailed.

The great ports of the world owe their importance, not so much to their geographical layout, as to the commercial activity of the back country, and

* Cons. Engr., New York City.

the Port of New York is no exception to this rule. Had there not been a natural port and harbor, the commercial necessities of the great State of New York would doubtless have produced one, for human ingenuity has known no limit under the pressure of commercial necessity. New York is one of the few great ports located on the sea and, therefore, escapes many of the problems affecting several of the other principal ports of this country and most of the famous ports of Northern Europe. To note some of the problems that New York has escaped, a contemplation of some of the difficulties that have been overcome, is reassuring; Philadelphia is 94 miles from the sea; New Orleans and Montreal are both examples of river development; Seattle and Portland are also examples of port development under adverse conditions; while, in Europe, the situation of the great ports—Liverpool, Manchester, London, Antwerp, Rotterdam, and Hamburg—brings to mind the natural obstacles that have been overcome in their development. All this suggests that, perhaps, the problems of the Port of New York, or of any other port, are not really National; they are local issues or problems. This was said once about the tariff, and although it took about twenty-five years to demonstrate it, it was finally generally admitted to be true. It is to be hoped that Americans learn more quickly now.

Most problems mentioned in regard to freight movements in the port, pertain to the stated necessity of placing the steamship and the car in direct contact, a matter that is not at all difficult when desirable. Many localities are available on the water-front of more than 500 miles, and the problem only becomes complicated when an endeavor is made to move freight cars around in congested localities into positions that are clearly foreign to their purpose or design. All the New Jersey portion of the water-front of the port is easily adaptable to such a treatment, if desired. The speaker recalls that when the so-called Chelsea improvements were built, none of the great trans-atlantic lines would allow railroad tracks on the piers, although the freight tracks of the New York Central Railroad were laid on the marginal street directly in front of the piers.

It is certain that quite a new type of engineer has appeared, a type that would aid any scheme provided there were sufficient funds ready for dispersal. Reference is not made to natural differences of opinion which must always develop in professional activities, but this new type only endeavors to silence the naturally curious by vociferous assertions of what they know, given, of course, without figures, and it would appear to be clearly propaganda for some hidden interest or the development of some commercial scheme. It is certainly a problem to obtain an unbiased opinion, although the experts for both terminals and ports were never more numerous. Bred to a certain extent by the conditions of war work, they are found in every problem, self-elected and ready to advocate almost any scheme for the expenditure of public funds.

The older methods of proving one's point of view must be restored if the engineer is to take a professional stand before the public. Many of the so-called problems are invented in order that the self-constituted expert or authority may get "his place in the sun", but the time must come when proper

analysis becomes the vogue. Thus, many so-called problems will disappear and much that is now written may be put away until needed.

The port problems of to-day do not differ materially and may be briefly stated as being concerned to a large extent with the commercial connection between the rail or canal carrier and the transatlantic ship. Commercial needs must dictate in the methods to be used, and no servile imitation of foreign methods will comply. The great systems of many of the foreign ports are not to be reproduced however effective a lot of cargo hoists may look against a sunset sky.

As the speaker sees the great problem of the Port of New York, it concerns the effective use of the water as a means of communication between the railroad terminals on the New Jersey shore and the points of delivery nearest those of consumption on a shore line of nearly 500 miles. For freight, there is nothing so economical as movement over a water lane, since no railroad yard admits of such expeditious and economical movement of freight cars as the slip between two piers, and the solution of many problems concerning freight movement may be best expressed by the term, "use the water". Do not think that it is necessary to go under it or high above it. The oldest means of movement, it still possesses all the advantages that it ever had and also is frictionless. It offers an almost ideal opportunity for movements on its surface.

As an illustration, it might be mentioned that there arrived in the Port of New York, recently, a barge carrying as much grain as could be carried by a full train load of about 70 cars, all within a bulk about 300 ft. in length, 35 ft. beam, and 12 ft. in depth, and this quantity of grain, amounting approximately to 2 300 tons, made the run from Detroit, Mich., to New York City in 8 days. Does not the picture speak louder than any words? Avoid the problems—"use the water".

RELATIONSHIP OF RAIL AND WATER CARRIERS

By William J. Wilgus,* M. Am. Soc. C. E.

In times like the present, when an impoverished world is practicing rigid economy as never before, it is to be expected that trade between nations will flow along paths of least resistance and, hence, through those gateways which, other things being equal, exact the least tribute in tolls and time from the rail and water carriers which meet there for purposes of interchange. This admitted, can it be denied that American engineers owe it to their countrymen to exert every force at their command to point out in what respect the principal ports of the United States are lacking and how they may be bettered? It would seem that the first move in this direction should be the bringing together of the transportation interests on land and sea, with a view to perfecting their related facilities in a manner that will best serve their common good.

The usual pier or quay, after all, is a joint terminal, not only for the ship, but likewise for the railroad and for the motor truck. Unfortunately, too often this common ground is under the exclusive jurisdiction of one of these agencies, with dire results to the others. For instance, a steamship line in the sole possession of a pier will seldom, if ever, provide proper space on it for tracks on which the railroads may place their cars for delivering and receiving freight direct. It may dictate to the railroads, without expense to itself, that the interchange shall be effected through the medium of trucking or of floating equipment with its added cost of breaking bulk and of tortuous water-front and marine operations. This situation which obtains to-day in the greatest American port—New York—was brought about originally by natural conditions which antedated the railroad area, and, later, was perpetuated through the provision in the seaboard rate which requires the railroad to interchange freight at the ship side rather than at the end of the rail haul.

The wastefulness of this process can be best illustrated by comparing it with the confusion, delays, and excessive costs that would reign in a joint railroad terminal where different gauges of the main lines and yard tracks would necessitate the breaking of bulk or transfer of car bodies in transit, within sight of their final destination, a condition too absurd for serious consideration.

The remedy for this manifestly unhappy situation lies in the conversion of port authorities and carriers, both rail and water, to the wisdom, or, rather, strict necessity, of abandoning the stingy pier policy and of building generously proportioned wide piers and quays on which there shall be ample space for transit and storage sheds, motor-truck driveways, and track layouts designed for continuous cargo handling uninterrupted by switching operations. All the great ports of the Old World, and even the principal ones of South America and of Canada, have taken this foresighted course, and in the United States the more progressive ports have rather timorously done likewise. There are, however, many ports, notably New York, where the narrow-pier policy still rules. In planning for the future then, let past faults be remedied and

* New York City.

wide piers substituted for the inefficient and wasteful narrow, trackless ones which have been inherited from the days of the sailing ship and canal-boat.

Another direction in which there is a dire need for improvement is the more extended use of mechanical equipment for reducing the expense of cargo handling and for expediting the release of ships and cars. For example, during the World War, the American Army in France operated in twenty to thirty ports at which in the last month of the war, November, 1918, there were discharged, by a variety of methods, nearly 1 000 000 tons of supplies at an average rate of 449 tons per ship per day, or, approximately, 1.10 tons per lin. ft. of ship berth per day. At one of these ports, American Bassens, there had been completed at that time a partial installation of electric gantry cranes, which despite many handicaps, such as untrained operators, poor lighting facilities, shortage of cars and stevedores, and insufficient "tuning up", made an average record of 717 tons per ship per day, equal to 1.8 tons per lin. ft. of ship berth. This was in marked contrast to the 371 tons per ship, or 0.9 ton per lin. ft. of ship berth, discharged daily at neighboring berths where non-completion of the gantries made necessary the handling of similar cargoes by ship tackle, not only with less speed, but also with greater damage to the supplies and with much more rehandling between ship, car, and shed by reason of the shorter radius of action of the ship tackle.

The effect of the gantry installation on economy of ship time and car time and on man-power is further illustrated by extracts from test observations taken at the same ports, as shown in Table 1.

TABLE 1.

Berth equipment.	Average tons per hook-hour.	Average tons per man-day (10 hours.)	Time of ship in port, in days.
Gantry crane	14.5	6.0	11
Ship tackle	8.4	3.7	16
Superiority of gantry crane over ship tackle.	73%	62%	31%

It will be seen that in this instance of mixed cargoes ranging from Quartermaster supplies to railroad materials, machinery, camions, guns, and fighting tanks, the modern mechanical equipment, even with the handicaps mentioned, was pronouncedly more efficient than the methods in ordinary use.

It is believed that these war experiences, which were borne out by those of the British Army in France, should be applied to peace-time commercial needs. At least, they are worthy of thought in connection with the planning of labor- and time-saving devices at the National gateways.

As bearing on the wisdom of a wide-visioned improvement of American ports, it will no doubt be of interest to cite the outcome of a recent study for a large port extension, which indicated that, although the widening of the piers for the accommodation of suitable track layouts, cranes, transit sheds, and driveways, would increase the construction cost over narrow piers more than 50% and reduce the linear space for berthing ships, the additional cost of the plant as a whole, including not only the piers but also the ships, cars, and

motor trucks, was only 8%, while the reduction in berthing space was more than offset by hastened speed of cargo handling and, therefore, quickened release of ships and cars. In consequence, it was shown that, with an undiminished annual tonnage capacity, the efficiency of the port would be greatly enhanced and the terminal charges, embracing ship and car demurrage, as well as labor, reduced more than one-third, after making due allowance for the increased fixed charges.

These figures, of course, are not claimed to be applicable to all times and places. They may be said, however, to serve the purpose of directing attention to the outstanding wisdom of carefully analyzing each port problem at which rail and water carriers interchange freight, both as regards adequate track facilities on piers and quays and also near-by, properly laid out, supporting yards for the storing and sorting of cars free from interferences with neighboring operations.

Several other features remain for brief comment. The unification of the management, under joint control, of rail and water terminals in the waterfront zone of each port is essential to a full solution of the port problem. With this, should go a co-ordinating belt line under the jurisdiction of the port management; an "open door" for the vast fleet of independent craft unpossessed of exclusive facilities—leased or owned; and working arrangements with the trunk lines, whereby freight consigned to the port shall be suitably grouped at distant clearing yards for movement direct to the particular location for which it is destined, without the need for intermediate reclassification or breaking bulk. There is much room for improvement through a further restriction of free storage which is now a wasteful burden on the rail carrier. Ample warehouses and open storage areas adjoining the piers and quays, with moderate charges, would go far to decrease this evil.

The argument so far has been from the standpoint of international trade. It should not be forgotten that whatever is done to increase the terminal efficiency of American ports may perhaps some day save the National existence when the stress of war may again tax the ports to their utmost. The lessons of the World War should prompt Americans to cure their ills in time of peace. Not to do so, at a modicum of the cost of a few $40 000 000 battleships, seems most culpable to one who witnessed the saving of Paris and, therefore, the cause of the Allies, through the presence of the outer belt line at that city, and who likewise saw how close the port of New York came to a breakdown, due to congestion and inefficiency, during the darkest days of the war. No American would like to see repeated the predicament of Washington in 1776, when the loss of the Battle of Long Island found him with nothing but rowboats with which hurriedly to rescue his army.

Relief in all these particulars would appear to be hopeless unless some competent central governmental agency, clothed with power, shall vigorously take up the problem in all its commercial and military phases, with the determination promptly to find and enforce the application of remedies. It is idle to expect that the ship interests and the many railroads will make any substantial united progress in that direction. Under Section 500 of the Transportation Act of 1920, the duty is placed on the Secretary of War to investigate this

problem in harmony with the declared policy of Congress "to promote, encourage, and develop water transportation service and facilities in connection with the commerce of the United States, and to foster and preserve in full vigor both rail and water transportation." Along with this, it is the duty, in the interest of the country at large, of the Interstate Commerce Commission now called on to underwrite the return on railroad investments, to look into and correct matters that affect the operating expenses of the railroads which are burdened with much of the wasteful practices at the ports, from which waste, the water carriers, often flying a foreign flag, are reaping the benefit. Then, it should not be forgotten that, Americans as a people, are vitally interested in the provision of efficient ocean port terminals for their gigantic merchant marine, as to which it is the duty of the Shipping Board to take action.

Can the Society perform a higher public service than to press on the Secretary of War the need for moving promptly and effectively in accordance with the Transportation Act of 1920, so that henceforth joint water and rail port terminals shall have planned and constructed in a manner that will best serve the country from both the military and commercial standpoints, (1) wide piers for the closest possible liaison between land and water carriers; (2) the best of mechanical devices for the economical and speedy transshipment of freight; (3) unified management of all transportation facilities within the water-front and contiguous zones at each port, including a co-ordinating belt-line railway; and (4) co-operation between the trunk lines, the ship interests, and the port managements for cheapening and expediting the interchange of freight and passengers at the ports? By seizing this opportunity for public service now, engineers may be instrumental in forestalling the future creation of port facilities on plans adverse to the true interest of the Nation.

In order that such a movement may be started, the speaker respectfully suggests to the Board of Direction of the Society that the question of the relationship of water and rail carriers at the ports be taken up with other National engineering societies, with a view to its forceful presentation, primarily to the Secretary of War, on whom the responsibility of investigating this matter is placed by law, and, secondarily, to the Interstate Commerce Commission and to the Shipping Board.

PORT ADMINISTRATION

By B. F. Cresson, Jr.,* M. Am. Soc. C. E.

Great ports cannot reach the condition of maximum efficiency, without some central co-ordinating authority to direct them, any more than any great business enterprise. It is no more reasonable to expect that a port can develop and function properly by leaving its development and operation in the hands of transportation companies, than to expect that the Pennsylvania Railroad could be operated efficiently with a separate board of executives and a separate policy in Philadelphia, in New York, in Chicago, and in Pittsburgh; nor if that great system had separate executives to handle its line haul, yard operations, passenger business, freight business, freight-houses, and passenger stations.

A central directing body is as necessary to the proper development of ports as a body of directors to the development of a railroad system. Without either, the situation is entirely against the modern principles of business; it is uncertain in its results and not in accord with modern civilization.

Time was in the history of practically every great port when the movement of commerce was simple; when there were comparatively few carriers, little competition, and plenty of room to expand; when commerce was attracted by natural advantages; where ships could dock and transfer their cargoes to land carriers with the greatest ease. It made little difference physically with the business of the port in those days whether docks were built, or quays or moles constructed; whether piers extended into the fairway, or whether canals were dug into the land. The important matter was to get contact between deep water and land in the easiest manner.

Before the creation of the great transportation systems, before the advent of the railroads with their powerful interests extending throughout the backlands, before the era of modern finance and business, the need of port administration as it is viewed to-day, did not exist.

In the days of ancient Tyre, land transportation was by wagon, or by skid drawn by man-power, horse, or oxen. The ships that sailed the seas were driven by the wind or by man-power at the oars. The cargo was handled into and out of the ship by men at windlasses; the situation was simple.

These conditions obtained, generally, at Venice, a great port in its prime, and at Amsterdam, which, prior to the supremacy of London, was an all-important port. These ports were laid out for sailing ships and for river and canal barges, and, even in London and in some of the older ports in Europe and in the United States, the early facilities as created were for sailing-ship service, without any thought or design for the service of railroads or of freight-handling machinery.

The situation is now far more complicated. With the advent of steam, it was possible to increase the size of ships, their speed, and their equipment. With the advent of the railroads, there arose the necessity of contact between their tracks and the ships. With the growth of machinery, a different design of port facilities became desirable. With the very many interests—financial,

* Cons. Engr., New York City.

transportation, operating, political—it has become a prime necessity to have some powerful authority to co-ordinate the facilities and the operations, and it is now an established fact that there must be public control which should extend not only over the harbor waters, but over the lands and the facilities adjacent thereto.

A modern port is made up of a multitude of different operating and administrative units. There are the transportation lines, the railroads, the steamships, the local marine operators, the river boatmen, the dockmen, the truckmen, the warehousemen, and the great financial interests directing private capital into profitable channels—all fighting for position—and not the least of these interests are those political. It seems impossible to divorce port control entirely from politics, and more than one port has suffered by political domination and by the ability abruptly and without redress to change the entire policy of its development and operation. The surest cure against political interference with the administration and development of the port is to appoint the commissioners in authority with overlapping terms of membership.

The public control by a central port authority does not mean the public ownership of port facilities. It does not mean that private investment must be converted into public holdings, nor does it mean that private initiative should not be encouraged and private money expended to produce modern terminal facilities. It does mean, however, that all these things should be harmonized by a degree of public control that will make effective a quicker and cheaper interchange between land and water carriers, will make the most advantageous use of the water-front and the waterways, and will weld the whole port into a terminal unit that will function with the highest degree of efficiency and economy.

The administration, ownership, and control of a port is not necessarily a part of the local government. There are many examples where the water-front of a city is entirely out of the control of the city itself and is under State or Government control, and, in many respects, this appears to be a right principle, as the port itself and the port facilities can be regarded in no case as strictly local facilities. They are in the service, not only of the city, but of the backlands, and, indeed, of a large part of the State and country tributary to the port.

The Port of Montreal is under the Dominion Government; the Port of Boston is under the Commonwealth of Massachusetts; and the Port of San Francisco is under the State of California.

In the Old World, London, is an interesting example of the trend of modernism in ports. For decades the greatest port in the world, handling the greatest tonnage, its supremacy was threatened by Liverpool.

The Port of London was under a number of private companies which owned the water-front and the terminal facilities and which levied from the commerce passing over the docks tolls sufficient to carry the investment and to yield a profit to the investors.

Liverpool was under a public trust made up largely of representatives of those companies using the port, and the returns from the use of the port were

needed only to meet the current expenses of running it, the interest on the public bonds issued to create it, and the credit necessary to enlarge it.

After an examination by a commission and a recommendation, Parliament, realizing the necessity for maintaining the pre-eminence of London, not only created the Port of London Authority with jurisdiction over the port facilities of London, but also authorized the funds necessary to buy out the private interests and place the ownership of the Port of London under a public trust. That this has been successful need not be discussed.

In spite of the World War, London has been proceeding with its programme of creating modern terminal facilities, and under its central control of ownership and operation will develop and prosper increasingly as time goes on.

In the United States, as a rule, private interests have initiated the development of the ports. They have sought to attract and control commerce by creating good facilities. They have acquired and held strategic water-fronts, but with the development of the railroads, and with the growth of business, there has come an appreciation of the necessity for a very marked degree of public control over port development.

The waterways are the public highways to the sea, and, as such, it is to the interest of the public that easy access to them be provided. This can best be done without the necessity of paying private interests for the right of so doing.

Private enterprise, however, need not be abandoned; there is ample room for private terminal works at all the ports, and they should be encouraged. Private domination of the water-front, however, should not be permitted, but all private interests should be co-ordinated into a general plan, all lined up in their proper position, with their proper functions to perform.

This discussion would be incomplete without referring to the situation at the Port of New York.

The first ship sailed into New York Harbor nearly 400 years ago, the explorer, Verrazano, being the first known European visitor. More than 300 years ago, Hendrik Hudson sailed up the river that bears his name, and, in 1624, Albany was settled and New York City two years later.

A century ago, there were no railroads. Eighty years ago there were a few railroad lines running short distances back from the shore. The Erie Canal, commencing 100 years ago, virtually marked New York to be the country's chief port.

In 1914, more than 8 500 ships entered and as many more left the port. More than 45 000 000 tons of commerce entered and left the port during that year. More than 200 companies operate ships into and out of the port. The 12 railroads which reach it, carried into, out of, or through, the port in 1914 more than 76 000 000 tons of freight. The value of the foreign commerce of the District of New York for the fiscal year of 1917, including gold and silver and foreign exports, amounted to more than $4 600 000 000.

The Port of New York lies in two States, New York to the east, and New Jersey to the west, with the dividing line down the Hudson River, down New York Bay, through Staten Island Sound, and through Raritan Bay. On one side of the port is the great city of New York which, for 50 years, has had its Dock Board or Dock Commission; on the other side, there are

fifty or more separate municipalities, and, until 1921, there has been no central co-ordinating authority to aid in the development of the port as a unit.

It may be argued that this great business which the Port of New York has handled indicates the absence of any need for central control, but New York has a harbor of unrivaled excellence, with 800 odd miles of good water-front, with an absence of any tidal difficulties, and a noteworthy freedom from fog and ice.

New York in its growth and its establishment as the financial center of the New World, however, is overtaxing many of its port facilities, with the result that costs are excessive, that lack of any joint rail facilities has caused the use of a large amount of valuable water-front for rail purposes, and delays and congestion which have existed here, in addition to costs, have tended to divert commerce to other ports. New York is not selfish; it does not desire business which should go through other ports, but it aims to maintain its own position and to accommodate the commerce which would naturally flow through it by reason of its geographical and financial position.

Realizing the necessity for some form of administration that would encourage the better use of existing port facilities and the development of new ones along lines of greater co-operative efficiency, and after a careful and painstaking examination and study extending over several years, the States of New York and New Jersey enacted laws, and, on April 30th, 1921, representatives of the two States met and signed a compact or agreement, which compact or agreement created the Port of New York District, embracing all of New York City on the east, Yonkers, New Rochelle, and other communities; and on the west extending beyond Paterson, Passaic, and New Brunswick, N. J. This control extends about 25 miles to the north of the City Hall in Manhattan, about 16 miles to the east, 23 miles to the south, and 20 miles to the west.

By the same action which created the Port of New York District, the Port of New York Authority was created with broad powers, which powers can be exercised on the acceptance of a comprehensive plan by the Legislatures of the two States. This plan in conference with the representatives of municipalities, civic organizations, and transportation interests, is now being prepared for submission to the next Legislatures of the two States.

This treaty or compact admirably expresses its purpose in the following words:

"Now, therefore, the said States of New Jersey and New York do supplement and amend the existing agreement of 1834 in the following respects: Article I. They agree to and pledge each with the other, faithful co-operation in the future planning and development of the Port of New York, holding in high trust for the benefit of the nation the special blessings and natural advantages thereof."

This compact or agreement between the two States has received Federal sanction by a joint resolution of the Senate and the House of Representatives in Washington, and by the signature of the President of the United States, on August 23d, 1921.

The Port of New York District and the Port of New York Authority are assured facts, sanctioned by the States and by the Federal Government; and thus, New York, the great port of the world in the volume of its tonnage and its business, has come to a realization of the necessity for port administration extending over its port district, and, in addition, will become able to handle more commerce, more rapidly, more cheaply, and more efficiently.

PIER DESIGNS AS DEVELOPED FROM QUAY DESIGNS

By H. McL. Harding,* Esq.

The purpose of this discussion is to determine the minimum width of piers whereby a constant uniform flow of miscellaneous cargoes through the pier may be accomplished without congestion.

It is generally accepted by terminal engineers that for the discharging and loading of freighters there is greater speed with economy at quays than at piers. Where there is ample room, and the physical conditions are favorable, it is desirable first to construct quays and, when more berths are required, to project piers. For an equivalent time-transferring capacity, a quay will require an investment of much less than half that of a pier.

There is more or less uniformity in the plan design of quays for ocean and Great Lake freighters. Each quay unit of a quay terminal is a little greater in water-frontage length than the longest vessel that may berth there. For ocean freighters this may be taken as 700 ft.

For each 700 ft. of quay length, the superstructure facilities consist of railway tracks, dray ways, paved, open dray areas, two sheds, overhead cranes with traveling conveyor hoists, and various surface carriers.

On this quay unit of 700-ft. length, the two sheds, each 200 ft. long, are placed, leaving 100 ft. of space at each end of the unit and 100 ft. of open space between the sheds. These sheds have a temporary holding capacity of 600 000 cu. ft. gross and 400 000 cu. ft. net, and are covered working areas, only for assortment and distribution, freight not removed within 48 hours being transferred to the warehouse.

It is necessary to have a supporting warehouse into which the goods may be placed at the expiration of 48 hours, the expense of moving to be charged against the goods.

Quay units may be taken as 150 ft. in width which is divided as follows: From the edge of the quay wall to the shed is 50 ft., with two railway tracks; then the shed, 50 ft. wide; and 50 ft. to the rear of the shed, with three railway tracks, making in all five railway tracks per unit. The outer 25 ft. in front of the shed is for dray ways and ship-side approaches and the remaining 25 ft. for the two railway tracks. The width of the shed may be increased to 70 ft., but, with steam railway practice, the narrower width is preferable.

The roof surface which is used chiefly for transfer and not for storage is of sufficient strength to sustain a load of 250 or 300 lb. per sq. ft. and is of sufficient height to admit of 20 ft. of tiering. Racks are often used in high tiering. At Manchester, England, freight is tiered as high as 40 ft. On account of the tiering which is done by overhead cranes and traveling electric hoists and tiering machines, it is necessary to reserve less floor space for longitudinal and transverse movements, than where there are chiefly floor movements. The expense and time for long horizontal floor movements are greater than for short mechanical vertical movements. There are a number of fixed overhead crane tracks perpendicular to the length of the shed and

* New York City.

on these and on the movable cross-tracks travel overhead hoists. These traveling hoists may be operated either from cabs or from the floor.

To the rear of the sheds the three railway tracks are spanned by gantry cranes similar to those in the front of the shed, unless warehouses are constructed, in which case standard bridge cranes supporting revolving gantry gib cranes would be used.

In the 300 ft. of open space on this 700-ft. length of quay is placed bulk freight, lumber, steel girders, and freight which is not affected by the weather. It is not desirable that such freight should pass through the transit shed, or that the expense and delay of lightering or of moving the ship to another berth should be incurred.

Similarly, in other mixed cargoes of which the greater part may be out-of-door freight, an open quay has been deemed necessary, even though there may be quite a volume of general merchandise for which there must be a rehandling. By the use of the open spaces described, the necessity will be obviated at a public terminal of open quays, especially where the cargoes are generally composed of different commodities. Greater speed and economy can be obtained by utilizing these open spaces instead of sheds. There are also fire-risk advantages in not having the sheds continuous over the whole area.

The warehouses of which there may be a large number are not included in the quay unit width, although they are indispensable to any successful terminal.

The aforesaid plan description and the enumeration of the mechanical and other facilities of the quay unit are given in order that it may be understood how the pier is derived from the quay.

The capacity of the quay unit should be measured not by the storage capacity of the unit shed and open spaces, but by the rate of flow of the freight through the unit. The reservoirs for the storage of goods are the warehouses, not the transit sheds. The rate of flow is preferably calculated by cubic feet per unit of time, therefore, the rate of flow is controlled by the volume, not by the weight totals.

A 7 000-ton ship has a net registered capacity of 700 000 cu. ft., or 100 cu. ft. per ton. This 100 cu. ft. per ton is taken as the unit of flow measure instead of the 40 cu. ft. per marine ton, which is much below the average of general merchandise. The 100 cu. ft. per ton is chosen to cover average maximum conditions.

To determine what maximum rate of flow may be required, this 7 000-ton ocean or Great Lakes freighter may have five hatchways or continuous openings. Each hatch will have two winches and in some cases four winches and two cranes. There will be, therefore, ten winches and ten cranes for each ship operation.

The function of the ship's winches is to draw the freight from between decks above the upper deck, where the draft is burtoned to the hook of the fall rope of the gantry crane and swung by the crane to the shore. In loading the ship, winches are used in stowing.

For example, assume a low average of only 60 cu. ft. per draft (1 200 lb.) in discharging and 60 drafts per hour per crane, which would be 36 000 cu. ft. per hour, making 360 000 cu. ft. per day of 10 hours, or 720 000 cu. ft. with two shifts. Although this 60 cu. ft. per draft may seem to be a low average, it is desired to make the estimates conservative.

There is a net holding capacity in both sheds of 400 000 cu. ft., or about 1 day's flow from the ship, and, in addition, about 250 000 cu. ft. in open spaces for coarse freight. The 650 000 cu. ft. makes a wide and deep channel for the flow. To prevent congestion, it is necessary, however, that a portion of the day's flow from the ship be kept moving as much as possible continuously through the shed.

A certain quantity of the inbound cargo will be discharged over the offside of the ship on harbor craft, another portion may be placed directly on cars or other land carriers, and some also will go directly into the warehouses.

The volume of each draft might be taken as 80 cu. ft. instead of 60 cu. ft. There will be variations due to the character of the cargo, but from 60 to 80 cu. ft. is a fair average.

It is evident, however, that provision must be made to care for a flow of from 36 000 to 48 000 cu. ft. per hour, or 360 000 to 480 000 cu. ft. per day of 10 hours. This, however, represents the flow capacity for only one ship at this berth; hence, the quay dimensions of 700 ft. by 150 ft. should take care of the flow of from 360 000 to 480 000 cu. ft. in 10 hours, but with little surplus capacity. If sheds have less height and a greater floor area, there should not be a gross capacity of less than 600 000 cu. ft. In order that the freight movements of lifting, tiering, and depositing within the covered areas may be done mechanically, one story is preferable to two, since there will be required only one overhead installation of machinery, while there would be two for a two-story shed, besides twice the superintending force. Where there are two or more stories, much of the transferring and handling is performed by manual labor.

At Manchester, England, the sheds have a clear height of 50 ft., which with the same ground area would give a capacity of 1 000 000 cu. ft. Freight can be taken down and transferred to any portion of the Trafford Estates (Manchester) for 12 cents per ton, which denotes great speed of movement.

Different figures may be deduced, but those mentioned will form a fairly close average for high speeds of transference and handling by machinery. Sufficient cranes and traveling hoists can be provided to keep up the flow from the gantry jib cranes. If, however, back of this quay there should be dredged a waterway and a berth should be provided for another ship of similar capacity, there is no doubt but that so much cargo flowing on this 150 ft. of width from the ships would result in delay, congestion, and the too often unnecessary detention of the ship.

Also, it is evident that on a pier only 150 ft. wide and 700 ft. long, in the accommodation of two ships, one would be far too narrow for rapid and economical conditions. The 150 ft., therefore, may be regarded as the minimum width of the quay for one full-length ship.

If two sections of a quay, with all facilities and equipment, are placed back to back giving a width of 300 ft., results could be obtained from this pier which would be nearly equivalent to those obtained from two quay sections each 700 ft. To express the plan in another way, one quay section may be regarded as bent back of another quay section, each constituting one-half of the 300-ft. pier.

On a two-unit pier of 1 400 ft., it is evident that there should be four quay sections each 700 ft. long, two sections on each side of the pier, but that each working-pier-berth-section should still be 150 ft. wide.

It is evident that because the freight of the outer sections of the pier has to pass between the two inner sections, an additional strip in the center of the pier may be required. This strip may be of sufficient width for three additional railway tracks, based on the supposition that the six inner tracks of the 700-ft. pier are designed to be worked to capacity. Railway operators know the necessity and great advantage in having ample trackage, but 300 ft. is often of sufficient width for a two-unit pier.

It is to be feared that where in the past the piers have been too narrow, there will come an era when they will be too wide, regardless of the value of the water-frontage or of the investment required.

The following conclusions may be drawn from this discussion:

First.—Whatever the determined minimum working width of a one-unit quay section of one berth and with the capacity and facilities for one full-length ship may be, the pier for two ships should be double the width of the quay and have double the facilities.

Second.—It is desirable to have railway tracks and dray ways in the center of the pier to the rear of and between the sheds, as well as between the sheds and the water's edge.

Third.—Where a pier is several units in length, and provision must be made for through freight movements between the land ways and the outside units, such increase in width should be designed to be in the central space of the pier.

Fourth.—A pier may be regarded as two sections of a quay with all facilities, bent back to back.

DISCUSSION

WILLIAM H. ADAMS,* M. AM. SOC. C. E. (by letter).—The Great Lakes-St. Lawrence Tidewater Association is an organization of formal State commissions, created by Legislative enactment in the States for which the Great Lakes form the natural outlet. Its work is the organization of public sentiment and the creation of public demand that this improvement be made, by means of the assembly and dissemination of information as to the work involved and the advantages which will accrue to the nation and especially to the Great Lakes region. Its power is being derived from the rising pressure of public opinion which is being moulded, not by oratorical fireworks, but by a carefully planned campaign in which the ammunition consists of technical facts, presented in logical order to the world of business and trade. A large part of its work is being done through chambers of commerce which, to-day, are the most effective means by which business men can get action in public affairs.

In 1919 the President of the Detroit Board of Commerce was appointed on the Michigan State Commission and early the same year the Detroit Board constituted a new committee of the Board designated "The Inland Waterways Committee". The writer was asked to assume the chairmanship of this Committee and to form a working committee from the Board's large membership of more than 6 000 business and professional men. As formed, this Committee included engineers, transportation men, real estate men, and plain "business" men.

It was early seen that there would be an immediate connection between the National project for the opening of the St. Lawrence River to ocean navigation and the local problems involved in organizing the Port of Detroit to take care of world commerce. Accordingly, studies were begun and publicity planned to prepare the city for this phase of the matter. In the fall and winter of 1919-20 a series of articles was run in the *Detroiter*, the organ of the Board of Commerce, reaching its membership and also the business centers of other American cities. This series also appeared simultaneously in the *Michigan Manufacturer and Financial Record*, a financial paper with State-wide circulation. These articles described the development of port facilities in other harbor cities, including lake and world ports. They were carefully prepared and intended to be technically correct, but were written for the business man. They emphasized the business aspect of the work. They told of the relative importance of the "hinterland" as a possible market, and gave records of commerce running back several years. Where available, figures on the cost of port development were given, and comparisons were freely drawn with the facilities for commerce at Detroit. This series ran for about six months. The articles were illustrated, to some extent, and were widely copied in trade publications and house organs. They inspired frequent editorial comment in Detroit and Michigan newspapers.

* Cons. Engr., Detroit, Mich.

Sandwiched into this series was the National publicity for the St. Lawrence Project. All National meetings, conferences, and conventions were carefully reported. Each such event is in large measure a repetition of former meetings, that is, little that is new is brought out at any one conference, although the general mass of data may be constantly augmented. What is generally missed by the engineer is that, while another meeting may not bring out any new data, it has afforded a new opportunity for some one to express an opinion, or for a community or organization to take sides, consciously or otherwise. The data may not be, but the promulgation of it is, news, every time it is done.

The faithful following out of this principle results in much repetition of the same or similar information, but it is probable that each publication reaches some new readers. It is a well-known fact, moreover, that the average reader pays only partial attention to what he reads. If a certain address were to be given in ten consecutive weeks, a new press story could be written each time. The curious fact, to the engineer, is that the general public by no means realizes that it is the same address or even the same set of arguments. Only a small part of one's audience interests itself in "arguments" anyway, or could tell why it believes as it does. About all the average man on the street gets out of a press story is that "the well-known Mr. So-and-So addressed the Blank-Blank Society last night on 'Port Improvements at Detroit' ", and he says to himself, "What a wide interest there is being created in this matter. There must be something in it." Then, he begins to talk about it, and what is more important, he begins to study how it will affect his own future and, in Detroit, he lays plans to acquire some of this water-front while it is cheap, "which will certainly be valuable", he says, "when these hopes are realized." He finds that some of his present interests will be improved by increased commerce and straightway becomes a booster for the proposed enterprise, although he actually knows little about it that would interest an engineer.

In the spring of 1920 the Board of Commerce began an investigation covering in exhaustive detail the actual interest Detroit and Lower Michigan would have in the proposed ocean route. This involved a considerable personnel of field and office workers under a paid secretary and its results were embodied in a book "Detroit and World Trade".* This volume is actually Detroit's brief for the opening of the St. Lawrence River, and was presented at the hearing before the International Joint Commission in October, 1920.

During the summer of 1921 an important Conference on the St. Lawrence project was held under the auspices of the Detroit Board of Commerce. It was attended by representatives of cities and States from all over the country. A three-day programme was presented, almost entirely technical, covering all phases of the subject. The work of this Conference received wide comment, nearly ten thousand columns of press accounts being noted within the ensuing months. Favorable public sentiment was aroused to a marked degree. This Conference was followed by a storm of requests for speakers at public and semi-public functions throughout the State. Boards of trade in other cities called for addresses; the University of Michigan put on a lecture in its summer school; civic clubs, Rotary Clubs, Stationary clubs, women's clubs,

* Copy on file at the Headquarters of the Society.

engineering societies, labor unions, lodges, and churches—every organization which so multiplies—and divides—the activities of a large city, clamored for speakers.

Each such event was heralded in the press; each one furnished "copy" for a press story afterward. Of course, an effort was made to fit the presentation to the audience. The appeal to real estate men was not the same as the lecture to public school audiences. Such a subject has so many phases, however, that little difficulty is had in adapting the subject-matter to the time and the place.

Following this July conference, it seemed evident that public sentiment was sufficiently aroused so that the main project could not be seriously delayed or blocked. It was decided, therefore, to form a new group for more intensive study of local conditions. In preparation for this phase, the writer attended the Chicago Convention of the American Association of Port Authorities, contributing an address on "Detroit's Port Problems", which was widely printed in technical and business journals and, including illustrations, was generally published in the Detroit press. The new Port Development Committee of the Board of Commerce was formally constituted in January, 1921, with the writer as Chairman, and a small working committee. Engineering societies and the many business clubs of the city were invited to form their own port development committees, the chairmen of which would be invited to serve on the Central Committee of the Board of Commerce. In this way, the interesting discussions of the Committee were carried back to the other groups of business men.

The work of the Port Development Committee during 1921 has been largely clearing the ground for action. An "Act" to create a Joint Port District, including Detroit and a number of down-river municipalities, was drafted and made the subject of several conferences attended by representatives of all the districts involved. This was accompanied by much press comment, the "Act" being printed in full in most cases.

It was early found that constitutional provisions would prevent the organization of such an inclusive port district, and work was begun on a constitutional amendment to remove the ban. With much attendant press comment, this was pushed through the Legislature, at Lansing, and the campaign for ratification is now on. Work is also in progress on a comprehensive "Act" to incorporate the Port District of Detroit, looking ahead to the next session of the Legislature in 1922.

The interest which has been created is so great that there is constant pressure for more news stories and interviews from the press. The Port Development Committees of Detroit are probably averaging at least a column a week in the principal dailies of the city and State in support of port improvement and the Lakes-to-the-Sea Project.

At the request of the Detroit Board of Education, and following a lecture before the assembled principals and assistants of the public schools, a small textbook is in preparation for use in the Seventh and Eighth Grades and in the High Schools. Debates are encouraged in High School circles, and data on both sides are supplied to contestants.

In conclusion, it should be mentioned that both Committees have had the aid of Mr. Tom L. Munger, a veteran newspaper man and writer, as Secretary. He can find "news" in what is to an engineer the baldest statement of well-known facts. Many of the simplest facts of engineering are absolutely unknown to the public. They only need to be related to some subject which has for the moment the public interest, and to be discussed in an interesting way to become "news", not once simply, but over and over again, as long as the public is still interested in the subject to which it may be, temporarily, related. A technical article, written for the engineer and published in an established technical magazine, will appear once only, be read and filed by a few engineers, and forgotten. If written for the general reader and published in the daily press, or in business publications, it will be read by thousands and reprinted for weeks and months. It may become the source for numberless stories by "hack" writers to appear in quasi-technical publications for years. An address by the writer, delivered nearly a year ago, is this month (August, 1921), being republished in a British magazine on the other side of the world.

Finally, newspaper space should not be under-valued. One is tempted to value only the front page as worth while, but, from long experience, it is evident that even the smallest inch of space on the least important page of the daily paper, is read by thousands. There has never been mention of the Port Development work in the daily press, even in the most casual manner, which has not been brought to the writer's attention by readers, many times.

Even the foregoing discussion, void as it may seem of interest to the general reader, will be the subject of paragraphs in the press calling attention to the need of Port Development in Detroit, the fourth city in the United States.

ARTHUR M. SHAW,* M. AM. SOC. C. E. (by letter).—In this discussion a far-sighted policy is advocated, of including in port plans, provision for "secondary" works, such as railway terminal and classification yards, belt-line connections, warehouses, etc., and an attempt is made to show that such facilities, operated as a part of the port works, will assist in avoiding congestion and reduce the delay of railway equipment and of ships.

Three cases are cited by the writer, which show lack of space for such facilities as are suggested, one representing the maximum in present American port development, one presenting more nearly average conditions, and a Central American port which is just beginning to be a factor in world commerce. These three specific cases are chosen as representing conditions which may be found in most American ports.

For commerce to achieve the highest possible degree of efficiency and the greatest growth, facilities must be provided for the prompt, economical, and orderly transfer of commodities from the point of origin to the point of destination. In an effort to improve conditions, a study of the causes of delay, excessive cost, and confusion is most illuminating. Such conditions are not especially apparent during periods of normal or light business, but become painfully obvious when an unusual or abnormal demand is made on

* Cons. Engr., New Orleans, La.

transportation systems and port works. The World War period was, perhaps, too abnormal to serve as a safe index, but the failure to achieve either speed, economy, or orderliness in the handling of the domestic and foreign commerce of the United States during the year that followed the signing of the armistice, would indicate that a study of the underlying causes of the most glaring defects might now be profitable.

The most obvious causes of delays to American commerce during past periods of unusually heavy business may be given as follows:

1.—Limitations of inland transportation systems, due to shortage of rolling stock and other causes.
2.—Congestion at terminals.
3.—Lack of wharfage and lighterage facilities.
4.—Shortage in the supply of ships.

As it is understood that this is to be one of a number of discussions, each of which will deal with some phase of port development or ocean commerce, the writer will confine himself to a discussion of the second point mentioned, although it is apparent that this has a direct bearing on each of the other three points. For the purpose of illustration, as already stated, three ports have been selected, representing what may be considered as the extremes and the mean of American port development, namely, the Ports of New York, New Orleans, La., and Puerto Cortez (Spanish Honduras). New York is far in the lead of all other ports of the New World in volume of business handled, and the list of commodities passing through this port includes practically every article used by civilized man. New Orleans is the second port of the United States in volume of business, but more nearly represents conditions as they exist in a dozen other ports of approximately the same rank. Its business is largely in agricultural products and in oil in bulk. Puerto Cortez has served as a port ever since the landing of the Spanish conquistador from whom it derived its name, but, until the last few years, it has not been prominent commercially.

At each of the ports mentioned, there has been serious congestion at times of heavy demands or there is evidence that such a condition will arise before any great increase in business handled may occur. Most great ports are the product of years of evolution, and any re-designing to meet new conditions must be made subject to the limitations imposed by existing improvements, many of which are not directly related to the functions of a port. On this account, especial (and usually expensive) methods are necessary to secure room for expansion and for the construction of auxiliary port works.

The following is a description of conditions which particularly affect expansion at each of the ports mentioned, with suggested means for overcoming some of the existing or prospective causes of congestion.

Port of New York.—This port has a great water-front, a spacious and well-protected harbor, and some of the most improved facilities for the storage and handling of cargoes. Tributary to the port are some of the most highly developed transportation systems of the world and, still, extreme congestion at the terminal yards, warehouses, and wharves occurs at times of heavy

movement of freight. If additional facilities could be provided for handling rail shipments and for the temporary storage of goods awaiting transportation, a great saving in handling would be effected and the lay-over time of railroad equipment and of ships would be reduced. This increase in facilities would include a belt-line railway connecting with as many trunk lines as practicable, railway classification yards, warehouses with both rail and water connections, and possibly sites for certain classes of industries which can be operated to the best advantage in the vicinity of large centers of population and convenient to facilities for inland and ocean transportation.

Along and near the water-front of New York City, there is no tract of land now available for such development as proposed herein, but, disregarding arbitrary State lines and considering as a logical part of the Port of New York, all that territory which might be used to advantage in the development of the port, there is still available (as far as any prior use is concerned) great areas of land almost ideally situated for the improvements suggested. These lands are known locally as the Jersey Meadows. The writer is not posted as to their present ownership, although it is assumed that they are controlled by individuals or private corporations and that, under proper procedure, they could be acquired for the purpose of public improvements. It is true that the utilization of these areas for the purposes mentioned would require certain improvements such as drainage and protection works, but no engineering problems would be involved, which have not been solved in a number of similar instances. These improvements will doubtless include the erection of levees to prevent tidal overflow, the cutting of diversion ditches to care for the drainage of adjacent high lands, the construction of a complete artificial drainage system (including sub-drains and pumps), and the filling, by hydraulic dredging, of certain limited areas. The drainage and protection of the City of New Orleans, and of various agricultural reclamation projects in the tidal swamps of Lower Louisiana, may be cited as successful examples of artificial drainage under similar conditions, although both the height of storm tides and the rainfall of the Gulf Coast section greatly exceed those of the New York district.

It may be of interest to note that, during certain years, more has been spent per acre in some counties of New Jersey in an effort to control the mosquitoes in the swamp lands than is required for the maintenance of drainage and protection works of a well designed Louisiana reclamation project. As an incident to the utilization of the Jersey Meadows for the purposes mentioned, a permanent solution of the mosquito problem would be reached.

Port of New Orleans.—The congestion at this port has not become as acute as at New York but, in many ways, the problems are similar. The Mississippi River serves as a natural harbor and affords deep-water wharfage for many miles along the city's front, but the demand for additional space is already insistent. The growth of the city was first along the river banks, and existing improvements make the cost of extensive port developments to the rear almost prohibitive. Partial relief will be afforded on the completion of the new "Inner Harbor Canal" which connects, by locks, with the river and which will add about 11 miles of water-frontage to the harbor. A strip 1 000 ft.

wide, along each side of this canal, and extending for the greater part of its length, has been acquired for port purposes, but no provision has been made for securing additional lands which will be required in the efficient operation of this element of the port.

The 1 000-ft. strips referred to should be used for wharves, wharf sheds, and warehouses, and for delivery tracks, but, supporting these facilities, should be distributing yards and other improvements of the nature of those suggested for the Port of New York. Adjacent to the canal are many acres of unimproved or slightly improved lands which could be acquired at this time at a cost that may be considered negligible in comparison with their ultimate value to the port. The city is now served by a publicly owned belt railway which could be extended to afford all the service required for this new development.

Unless a far-sighted policy is adopted, which will provide for the early acquisition of vacant lands in the vicinity of such cities as New Orleans and New York, for the purpose of port development, it will be only a few years when other interests, not directly concerned in commerce, will secure control of the most favorably situated tracts and make more difficult the improvements which are so obviously required.

Port of Puerto Cortez.—This is a port now "in the making", although local tradition maintains that it was the first continental port of call of the Spanish conquistador, Hernando Cortez. Until very recently, the port facilities consisted of a commodious and safe harbor, a decrepit timber wharf, and a single-track railway leading to the interior of the country. Recent improvements include a reinforced concrete wharf, steel wharf sheds, mechanical loading equipment, and a convenient system of tracks for making rail delivery to ship side.

The Cuyamel Fruit Company operates from this port and has been instrumental in securing the improvements mentioned and, also, with the co-operation with the Government of Honduras, is fostering a varied development of the interior. At present, it is probable that bananas form at least 90% of the exports from this section of the country, but it is realized by those who are most interested, that a business built up on this one commodity is standing on a slippery foundation, and a substantial increase is now under way in cattle raising, sugar plantations, and general farming. It is reasonable to expect that, within the next few years, the present facilities of this port will be outgrown. Ample opportunity exists for the extension of the wharves along the harbor front, but of the "hinterland", there is none.

The Town of Puerto Cortez is built along a single street which occupies the crest of a ridge of beach formation. This ridge carries the track of the National Railway of Honduras, a footpath on each side of the track, and, in a few places, is wide enough for buildings fronting on this "street", although most of the buildings rest on made ground or on "stilts". Street traffic is confined to pedestrians, wheelbarrows, and such vehicles (railway velocipedes, push-cars, etc.) as can be run on the railway track. There are no saddle or draft animals in the town.

Back of this strip of high ground is an "impenetrable" swamp, the word "impenetrable" being used in its ordinary sense which is generally understood

as not applying to exceptionally hardy explorers or to almost any engineering party. The problem of expansion of the secondary port works and of the town itself can be solved only by the reclamation of adjacent swamp lands, as has been suggested for the Port of New York.

In each of the ports described, the need is shown of additional space for handling present business and for future growth. Exact parallels will not be found in other localities, but it is believed that, in general, the problems are similar and that their early solution will contribute to the upbuilding of American commerce.

Unless their transportation systems and ports can be relieved of unnecessary handicaps, Americans cannot expect to compete successfully in the handling of the world's commerce. Obstructions not only affect adversely the American merchant marine, but also hinder the development of American industries and will constitute a real menace to American armies in time of war.

T. F. KELLER,* M. AM. SOC. C. E. (by letter).—The question under discussion, "National Port Problems", is one, which, when studied from the standpoint of one interested in the improvement of the water-front of the City of New York, brings forward the thought that that water-front is a National port problem. The volume of its business and its close relationship with the remainder of the United States makes the problem a National one.

The City of New York has laid down a comprehensive plan for the development of the Port of the City of New York. There has now been advanced a plan, and the initial steps are being taken, to construct a tunnel under the Narrows, between the Boroughs of Richmond and Brooklyn. When completed, this tunnel with its rail connections, will effect the entry of all the transcontinental lines into the Stapleton Development with its 2 000 000 sq. ft. of pier space and 26 000 lin. ft. of berthing space for overseas steamships, will also open up for intensive development the magnificent Jamaica Bay, and will actually bring the railroads to the ocean.

On the northern side of the city, Flushing Bay will be thus made ready for development, and the wisdom and necessity of deepening Hell Gate to 40 ft. at mean low water will have been proven. Incidentally, connection will be made so that the vast undeveloped shores of The Bronx, along the East River, will attract attention for steamship and industrial purposes.

This tunnel and its necessary connections will bring the railroads through the heart of the Greater City, will open for development the outlying sections, all on deep water, and will serve for all time to show that the City of New York with its responsibility to the Nation has not been remiss in developing its resources.

At present, the city has about 85 miles of berthing on the sides of piers. It can be said, without fear of successful contradiction, that the proposed tunnel, with its necessary rail connections, will add a similar amount of berthing to its facilities, bringing sea and land together, and when served with

* Chf. Engr., Dept. of Docks, New York City.

all the cargo-handling equipment demonstrated to be necessary and efficient, the City of New York will have played its part in solving the "National Port Problem."

The stimulus thus given by the premier port of the world cannot but help in urging water-front development of other American ports to the end that the rivalry created will place all these ports on a high plane of efficiency and will solve the National port problem.

HARWOOD FROST,* ESQ. (by letter).—The writer will discuss herein only one of the many topics that come under the subject of "National Port Problems", namely, the necessity of the conservation of labor at terminal ports.

The term "conservation of labor" rather than "saving of labor", is used, as the mention of labor-saving is too frequently and too generally associated with the dismissal of men, the reduction of the force; and, as a consequence, the introduction of so-called labor-saving devices in any kind of a plant has been bitterly opposed by "Labor" under the mistaken idea that their use would deprive many of the men of their jobs. Facts, however, have not borne out this idea, but rather the reverse, as has been fully demonstrated by the history of printing as affected by the development of the linotype machine, and of many other industries as affected by similar time and labor-conserving equipment.

In the past when labor was plentiful and cheap, it was bought and sold as a commodity, with little thought of its conservation in the manner of the conservation of National resources, such as water power, forests, fuel, etc., and little consideration was given to labor by the nation generally as an important part of its resources. "Labor" looked on mechanical material-handling appliances as enemies, and their introduction was always accompanied by fears of strikes or other labor troubles. With an increasing scarcity and cost of common labor, however, a feeling is developing that such machinery may be looked on as an ally, a means of reducing the drudgery of the laborer's work, of conserving his strength, of increasing his efficiency and enabling him to earn a greater income, thus, in turn, improving his social position, giving him a great buying power in the commercial world and generally elevating him to a higher plane of citizenship.

The problem of labor has always been closely associated with the equally important problem of the economic handling of materials; the two problems are of most ancient origin and go hand in hand. There is no doubt that the transport, lifting, and placing of the huge blocks of stone used in the construction of the great Egyptian Pyramids presented serious problems to their builders, or that serious problems were also presented to the builders of the wonderful aqueducts, temples, roads, and other monumental works of Rome and Greece. Yet, with only a rudimentary knowledge of mechanics, and by the use of the simplest mechanical devices, such as the lever, wedge, pulley, etc., those problems were met and successfully overcome. Go as far back as one will into the historic and prehistoric past, and evidences of these associated problems of labor and material handling are found. These problems have ever existed; their solution has formed the basis of comparative civilization;

* Chicago, Ill.

they have had their effects on history, on society, on industry; they have been the determining factors in wars, and have made and unmade nations; and they have regulated commerce on sea and on land.

The same problems of labor and of methods of handling materials still exist. They seriously affect the daily lives of the people; they make for success or failure in industries; and they regulate the prices of commodities. These problems have always existed; their solution only is different. The ancients solved their problems by the use of vast numbers of slaves, and time was no object. There was no thought of the conservation of anything. So with Americans, when labor was plentiful and inexpensive, there was waste and little thought of it as a commodity of value, to be conserved. With the tremendous drafts on the manufacturing and labor resources of the United States caused by the World War, together with congested terminals and transportation difficulties, however, the people were brought to a conscious realization of the value of labor as a basic commodity and, also, that in the utilization of labor-conserving machinery for handling materials, Americans had not kept pace with other countries. In order to keep costs within limits that would leave a fair margin of profit, whether in the handling of goods through a marine terminal or through a manufacturing plant, it was found to be absolutely necessary to conserve the available labor supply and to raise the efficiency of the man-power by the most extensive possible use of mechanical appliances.

Through the necessities of their overseas war operations, Americans have suddenly developed into a more or less maritime people; they have greatly increased the number of their terminal ports; they aim to see the American flag flying on American ships in all parts of the world; in short, the war forced them into the business of ocean transportation and they now desire to compete for the world's trade against older and more experienced maritime nations. They, however, continue to ignore at their terminal ports the very methods and practices that brought about the efficient and profitable operation of foreign ports, and this in the face of the fact that these same foreign ports are gaining a certain amount of their maritime strength and advantage at the expense of Americans, that is, by the use of large quantities of time and labor-conserving equipment produced by American brains and industry. America has invented, and manufactures more modern freight-handling machinery than any other country in the world and uses comparatively less.

There are a number of reasons for this condition, which it is not the writer's purpose to discuss; he desires, however, to trace briefly one of the results of the condition. The waste in labor at American terminals in the handling of freight has been said to be more than $400 000 000 annually—it may be more or less, but, in any case, the figure is sufficiently high to warrant consideration and to impress one with the magnitude and importance of the problem of this wasted effort. This $400 000 000 of wasted effort may be looked on as representing at a fair rate of interest, a labor capital of $8 000 000 000 tied up by American terminal inefficiency; but, also, consider that, in the passage of goods of any kind between producer and consumer, through the hands of jobbers, wholesalers, retailers, etc., any item of waste

is multiplied by each middleman in just the proportion he increases his selling price above his cost, and that a waste at the source will cost the ultimate consumer about four and one-half times the original waste. On this basis, the $400 000 000 of unnecessary terminal waste would increase the cost of goods to the ultimate consumer by nearly $2 000 000 000. Further, since the finished product of one concern is frequently the raw material of another, the cost of production to the second concern is increased by the multiplication method with every handling, just as the price of commodities is to the consumer. This progressive increase in the cost of wasted effort most certainly has a serious effect on two of the most important problems of the day—the cost of living and the cost of production.

It is evident, therefore, that in the handling of the hundreds of millions of tons of miscellaneous freight which flow through the port terminals of the United States, wasteful methods add to the burden of the consumer, while quick and efficient methods reduce this burden.

The general public, however, does not seem to understand this. There are many men, business men, handlers of the essentials of life, as well as the consumers, who fail to comprehend why they should be interested in the terminal affairs of New York, New Orleans, or Seattle. They readily accept an increase in price said to be due to increased labor costs or increased freight rates, but they do not seem to realize that anything which affects handling costs in any one of the large terminals, or of goods anywhere in storage or transfer, becomes a matter of direct concern to each and every one of them, because they have not given consideration to the close and vital relations that exist between general business welfare and transportation service, that is, the various factors involved in the distribution of commodities. Nor do they realize the fact that whenever the cost of any single element of transportation, such as the unloading of boats, piling, or otherwise moving, of goods in storage, or the loading of trucks, rises above a fair normal level, it becomes a tax on business generally, and the ultimate consumer must pay for it.

The elimination of wasted effort in the handling of merchandise at terminal ports is a matter of public concern, it is a problem of the whole people; it is a National problem, affecting every one, in every locality, in every station of life. This burden of unnecessary taxation and waste cannot altogether be eliminated, but it can be materially reduced by the substitution, whenever possible, of machines for men, and thus by reducing this "cost of lifting", the "cost of living" also will be materially reduced. Any general reduction in the cost of moving goods through the terminals is certain to have its effect along the entire line, and the general public, like the ultimate consumer, is certain to share in the savings, as neither the middlemen, nor the transportation companies, nor any other single interest, can appropriate it all.

L. F. Bellinger,* M. Am. Soc. C. E. (by letter).—There has been much in the newspapers recently concerning the old DeWitt Clinton train with its diminutive locomotive and passenger cars of about one-twentieth the weight and capacity of those of the present. This train is really interesting to the

* Lt.-Commander, C. E. C., U. S. N.; Dist. Public Works Officer, 8th Naval Dist., New Orleans, La.

present generation, because of the small size and small capacity of the passenger coaches and freight cars, namely, twelve passengers per passenger car inside, and only a few thousand pounds per freight car. At present, it would seem to be impossible to develop economical transportation with the numerous carriages of the DeWitt Clinton size required for a given volume of freight. There are many indications, however, that the container or the original package is to be reduced to approximately the size of the DeWitt Clinton freight car. Steel containers of approximately this size are used in the Warrior River Barge Transportation Service, and wooden containers are used to some extent on the railroads. These containers are taken from barges, lifted bodily by derricks, and placed on flat cars which make rather economical the interchange between barge and railroad train. Especially in less than carload lots, freight consigned to individuals is easily stored in these cubicles. If their total weight is limited to about 5 tons, the entire cubicle can be lifted from the flat cars and placed directly on the ordinary 5-ton automobile truck, delivered to the consignee, unloaded, and the container returned to the railroad.

The economical handling and storing of these cubicles is a matter of detail. At present, much of the package freight is unloaded by ordinary hand trucks, which will carry from 50 to 500 lb., from the freight car to its proper place in the freight-house, thence by hand trucks to automobile trucks, thence to the consignee's storehouse. As now used, the cubicles, with proper design, can be handled by motor-driven piling and stacking machines, carried from the freight car, and placed wherever desired in the freight-house if the cubicle is placed on skids in such a way that the stacking machine can take hold beneath. With the cubicle and the motor-driven stacking machine, one man can handle 5 tons on one trip as against the ordinary 500 lb. maximum with the hand truck.

The devices outlined make for cheaper transportation from point of origin to ultimate destination to the consumer. Heretofore, the effort has been made to reduce the cost of rail transportation per ton-mile until the ton-mile cost in the United States is reduced to its lowest limits, provided the large and expensive freight cars are fully loaded. By means of the cubicles a cheaper freight car is used, namely, the flat car, and the cost of transportation, especially through the freight-houses, is very much reduced.

The connection between the preceding discussion and the increase of port facilities in the United States is not at once apparent. Just as the intention in the past has been to reduce the cost of freight per ton-mile, so the intention of port engineers in the past has been to have a port which would be capable of easily receiving the largest deep-draft steamers that have been built. In order to accommodate these much advertised, maximum sized ships, each small port has dreamed of increasing its facilities so that a ship of maximum size could lie at its wharves and, in the immediate future, rival New York in its commerce. It is believed that the time has come to take up the question of the use of the shallow ports of the globe, to utilize them for the benefit of the remainder of the world to distribute the traffic which is now so concentrated

in the deep-draft ports, and thus to reduce the cost of package handling which results in excessive terminal charges and adds so largely to the total cost of distribution paid by the ultimate consumer.

It is well known that the cost during the time a ship is in port is a very material fraction of its cost of operation. It is also well known that any reduction of time in port adds materially to the earning capacity of the ship. To a certain extent the smaller the ship the shorter is the time to unload and the less idle time is necessary in port. Reduction in the size of the ship can be carried so far that the demurrage is small, but the earning capacity of the ship while in transit reaches the vanishing point. On the other hand, the very large ship wastes so much time in port and, at present, requires so long a time to secure a full cargo that the ship of maximum size is now a losing proposition, which is also true of the very small ship.

There are numerous landlocked bays and harbors in the world, which will permit, with very little or no development, barges and ships of drafts of 10 ft. or less. These harbors were of value about the time of Columbus, or earlier. At the present time, they are unused because of the lighterage costs which occur in handling freight with hand trucks or on the shoulders of stevedores. The freight is handled from the freight warehouse ashore to the barges and again from the barges to the holds of ships lying off shore. Thus, the cost of transportation between point of origin and point of ultimate destination is made too great. There are a number of ports in the world which have spent millions of dollars to secure channels and slips alongside piers that will permit of ships of a draft of 30 to 35 ft. or more. The millions of dollars spent in securing facilities for ships of maximum draft come from the ultimate consumer indirectly in the form of taxes, but, nevertheless, it adds to the actual cost of transportation between the point of origin and the point of ultimate destination.

Instead of increasing the depths of channels, instead of increasing the depths at piers, and in spending additional millions for port facilities, it is believed the time has come again to consider the ports which will accommodate ships of medium draft, and to rehabilitate old grass-grown piers of ports which, although not dead, are at least in a comatose state. There should be a distribution of traffic from the present few large deep-water terminals to water terminals of medium depth, just as at present there is a change in the development of a city from the one large loop district, or the single business center, to several well distributed so-called "civic centers", each fairly complete in itself. When this distribution is effected the following advantages are found to exist: Low, fixed, capital charges; low terminal charges; low cost of land; low cost of building materials; low house rents; and low cost of distribution of food products to these small cities, all of which result in a low cost of living. Each advantage in itself bears directly on a lower cost of labor for those living at the "civic centers", or at the water terminals of medium depth.

Wherever there is a low cost of labor and a low cost of building materials there is a chance to utilize, by means of the cubicles mentioned, a low cost of handling exports from small ports through the small or medium sized ships to the consumers in various parts of the world. The utilization of the medium

sized ships through the medium sized ports will conduce to low freight costs from the point of origin to the point of ultimate destination, through the low costs of handling freight at such ports.

Any reduction in cost of production or of transportation will aid in stimulating trade between Europe and the United States. Any stimulus to trade accelerates the circulation of commercial products and gives debtors a chance to pay their debts and to increase the wealth of the world available for business extensions. Furthermore, it conduces to that international good feeling so necessary to restore business confidence and business health. Anything which will relieve Europe of its sufferings from business "gout", will loosen up the "rheumatic joints" of business in the United States.

It is believed, therefore, that attention should be given not so much to expensive port development involving millions, but to the increase in the use of the medium sized ports which will require comparatively little capital and yet will enliven many different sections of the body politic now in need of resuscitation rather than rehabilitation. In a country the inhabitants of which have a steady income, although small, the people are far more satisfied than those of a country or city where high priced wages obtain, but where work is intermittent. The idle time is used by Satan for the purpose of stirring up dissatisfaction, destructive criticism, strikes, and ultimate revolution.

JOHN H. MCCALLUM,* ESQ. (by letter).—The writer is deeply interested in all port development, especially as it affects all ports of the United States.

As the Port of San Francisco is the gateway to the Orient, the California State Harbor Commissioners are very desirous of furnishing it with the most up-to-date and economical equipment and devices for handling such commerce, and any information that can be gathered, which would assist them in furnishing such facilities and equipment, is eagerly sought. Those who are actively engaged in commercial pursuits and who use this port are of the opinion that the facilities are quite up to date.

The writer has been a member of the State Harbor Board for the past ten years and is quite free to admit that whatever success has been obtained for the Harbor of San Francisco is due largely to the spirit of co-operation between the members of the Board and all factors interested in the port.

During the period of reconstruction which began in 1911, the engineers of the Harbor Board were assisted very greatly by an Advisory Board of Engineers of large experience in water-front construction. In 1917, the rules and regulations, including the system of port revenue and penalties for the use of piers beyond the free period, were completely changed, this change being worked out with the co-operation of a committee appointed by the Board, consisting of those vitally interested in the commerce of the port. The new system has worked splendidly, and especially as it applied to penalties, for, as this was in a great measure the suggestion of the users of the port, they were bound thereto. In 1917, the Board also appointed an Advisory Committee of twenty men doing the greatest business through the Port of San Francisco to advise

* President, Board of State Harbor Commrs., San Francisco, Cal.

with it from time to time on vital problems of the port. This Committee is composed of importers and exporters, ship-owners and operators, representatives of the Chamber of Commerce, Warehousemen's and Draymen's Associations, the railroads, etc. The services of this Committee have been invaluable to the Harbor Board, and its unselfish devotion to the interests of the port has been wonderful. The writer is a firm believer in the policy of consulting the interests that are using the port facilities as to its development.

One of the great engineering problems confronting San Francisco and the Bay region is that of constructing a bridge from the San Francisco side to the Alameda County shore. Some study has been given thereto and a report has been made, but the problem seems to be still unsolved.

FRANK W. HODGDON,* M. AM. SOC. C. E. (by letter).—Ports, as usually known, are points on the sea coast at which merchandise can be transhipped from land transportation to sea transportation, or *vice versa*.

In order to have a port, there must be merchandise to be transported and merchants to control it. If there is no merchandise, there can be no port, and if better facilities are furnished at another port, the merchandise will go there and the port with the lesser facilities will disappear as such, as has been the fate of Salem, Mass. In former times, vessel units and cargoes were small, and land transportation was adequate to convey any bulky merchandise only for short distances, so that many small ports existed which have now disappeared. As railroads were built and developed, they took up the distribution of bulky merchandise and delivered it far inland and brought to the sea the products of the interior. At the same time, the vessel units increased in size, with the result that the facilities furnished by the ports had to be radically changed and enlarged, and the assembling of cargo units could only be done economically by reducing the number of ports and concentrating the business at a few large ones at which the railroads could concentrate. This concentration will continue until the amount of business at any port exceeds its capacity, when it will become necessary to divert some of the business to other ports.

In general, merchandise will take the most direct route, other things being equal, but many things happen to change this, such as rates and facilities for handling the merchandise, congestion on the direct route, etc. The facilities furnished by a port are both fixed and variable. The fixed facilities are the channels, wharves, docks, warehouses, etc., the railroads and highways. The variable facilities are the vessels, railroad cars and equipment, and trucks. These are the facilities only to handle the merchandise which is furnished by the merchants who are the real creators and life of the port, and without which it could not exist. Usually, the port itself controls only the channels, wharves, docks, and, sometimes, some of the warehouses, freight-handling equipment, and railroad yard tracks on its own property. All the vessels, railroads, merchandise, trucks, etc., are owned and controlled by others.

From this, it will be seen that the port merely offers an opportunity to carry on a business over which it practically has no control, except to offer the best

* Chf. Engr., Mass. Dept. of Public Works, Div. of Waterways, Boston, Mass.

practicable facilities to induce business to pass through it. The merchants control the business and can practically make or break any port.

Business like natural forces will follow the line of least resistance. A port naturally situated so as to offer the best conditions as to rates and facilities will secure the most business. New York is situated at the mouth of the Hudson River and, with this inland waterway supplemented by the Erie Canal, was especially advantageously located. It thus became the foremost port of America, attracting business from all over the country, even though handicapped by not having the opportunity to run its railroad trains on to the piers and thus be able to handle merchandise directly between cars and vessels.

The large volume of business and the low costs of land transportation induced by the low grades of the railroad and the competition of the inland waterways attracted more merchandise, so that vessels were attracted since they could usually find a cargo waiting, even if advance arrangements had not been made. At smaller ports, however, such spot cargoes cannot generally be found, and if a vessel brought a cargo to one of the ports without having engaged a return cargo in advance, it would have to sail in ballast and seek a cargo at some other port. This would increase the cost of operating the vessel, and this increased cost would have to be made good by increased freight rates when a cargo was secured. This would make the small port less desirable as a shipping point compared with one which could furnish spot cargoes at most times and thus, again, increase the desirability of doing business in the larger port. Large ports have more frequent sailings of regular lines and tramps than the smaller ports, and small shipments will find more frequent opportunities there and less likelihood of delays.

As already stated, in order to be successful, a port must be properly located, with efficient land transportation tributary to it and a back country capable of furnishing sufficient merchandise to load all the vessels frequenting the port and absorbing all the merchandise which is brought to it. The port must be well equipped with channels, wharves, docks, warehouses, etc., properly to handle the merchandise, and must also have merchants ready to handle the business. A port, to be successful, must first have the business and the wharves, channels, and other equipment, and then the ships will come.

The various ports of the world are managed in a number of different ways: Private ownership including ownership by railroad and corporations; and public ownership such as State, city, or other political divisions. These different methods take no cognizance of the merchant who really controls the port by furnishing the business done through it, and who, if he had some interest in the management of the port, would have a great inducement to persuade other merchants to use it and, thereby increasing its business, tend to reduce the cost of sending his own business through it. Also, the merchants would be able to decide with first-hand information to just what extent it was advisable or profitable to install better or additional facilities.

The method adopted by the Port of Liverpool, England, one of the most successful ports of the world, is based on the idea that the merchant who does business through the port is the person who should manage it. The Corporation of the Mersey Dock and Harbor Board is without capital or shares,

and its credit is based on the prosperity of the port and the value of the property owned by the Corporation. The electors who annually elect the officers of the Corporation are the persons who, during the previous year, have paid port and dock charges of not less than £5. In order to be eligible to be a director, a person must have paid not less than £25. The Directors receive no compensation, but it is considered such an honor to be one that the office is always sought for.

By law, the port charges must be fixed to pay the interest, sinking fund, and maintenance. All improvements and extensions must be paid from the proceeds of loans authorized by the Government. The Secretary and Engineer of the Board are the paid executives. In this way, the merchants have control of the port, and it is to their interest to furnish it with as much business as they can, in order to keep the costs down, as the business is done at cost.

One difficulty at some of the Atlantic ports of the United States, is the inequality of rates when part of the wharves are owned by the railroads, and part by the city, State, or private owners. The railroad companies use their wharves as one of the facilities of the railroad, and make no charge either to the vessel bringing freight for the railroad, or to the goods which are sent over it, other than the regular freight rates. That is, there are no charges for wharfage or dockage, except on goods which are shipped to or from the wharf by other means than by the railroad which owns the wharf. Frequently, the charges for freight on goods brought to or from vessels at a railroad wharf, are less than on similar goods brought to the port for local consumption, although the terminal costs of the railroad are greater for the vessel, than for the local business.

Public or private wharves, of course, cannot compete with railroad wharves on their basis, and some means should be found by which charges should be made, by which the actual cost of facilities at a port should be collected on all goods passing through it, and, if possible, this should be made equal at all wharves. In order to do this, the whole port should be under one control and management, either public or under public supervision. The exact form is not necessarily the same in all ports, but some form of operating the whole port, as a unit, seems to be essential.

M. G. Barnes,* M. Am. Soc. C. E. (by letter).—Since 1914, measured by cost of rail transportation, interior points of the United States have been placed twice as far from the seaboard as formerly. At best, the wheat belt of the United States is handicapped in the world markets because of its great distance from the seaboard. Increased rail rates have aggravated this condition of affairs, lowered grain prices on the farm, and placed the American farmer at such a disadvantage as to limit his foreign market and, indeed, foreign grain may be delivered at the seaboard cities at a less cost of haul than from the grain belt of the United States. Since 1914, the cost of transporting wheat by rail to the seaboard has increased from 12 to 15 cents per bushel. The cost to domestic consumers in the Eastern States has increased to even a greater extent.

* Chf. Engr., Div. of Waterways, State of Illinois, Chicago, Ill.

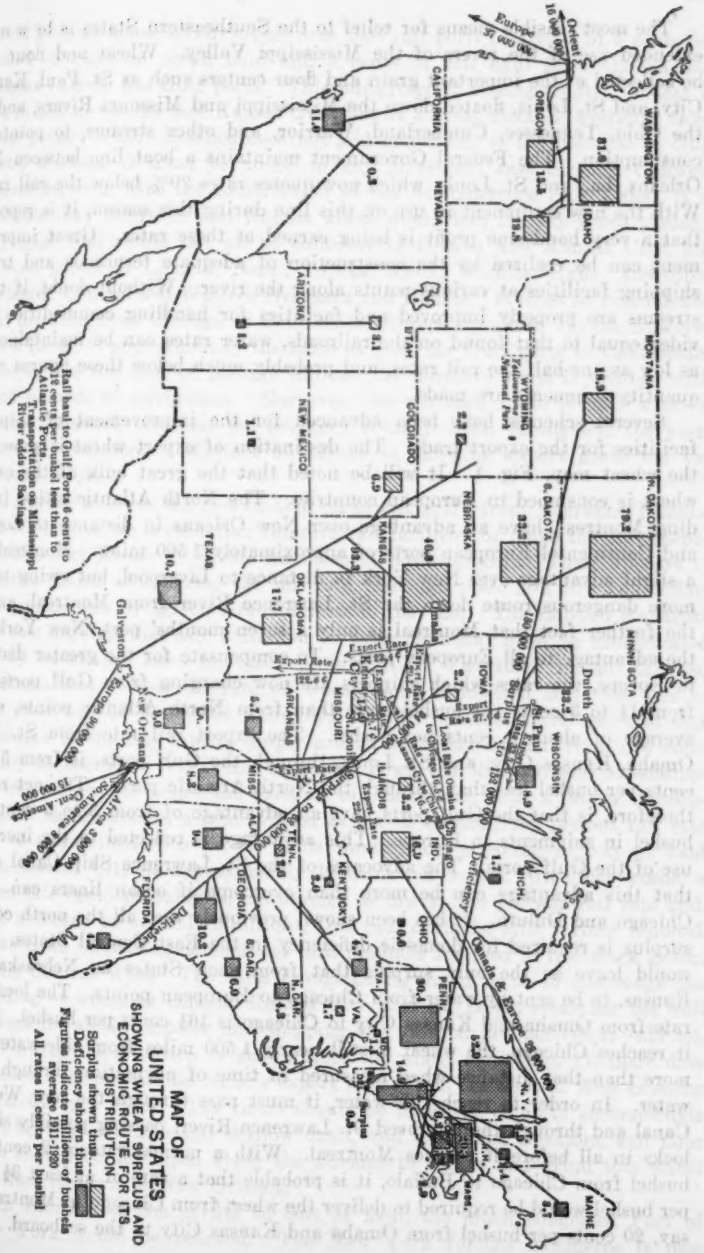
Based on the past ten-year average annual production of 794 000 000 bushels, these higher freight rates represent a tax on the producer and consumer of at least $100 000 000 annually. This would indicate that on a 10% basis, $1 000 000 000 might profitably be spent to reduce the cost of haul on wheat to the pre-war level; and, of course, if wheat could be hauled at pre-war prices, other commodities would profit in like manner.

Fig. 1 shows the location and quantity, or volume, of the surplus wheat of the United States, and its destination, the figures having been compiled from the records of the U. S. Department of Commerce for the past ten years. Although the destination of the export wheat is roughly accurate, the ports from which it is assumed to move are not the actual ones, but more nearly represent the economic lines of movement based on present rail-transportation facilities. During the open season of navigation, part of this wheat travels by rail and water to the Gulf, and a greater part by rail and water to the Eastern States and the Eastern seaboard, but probably not sufficient to change the routing suggested.

Various suggestions have been made for the improvement of transportation facilities and especially as it affects the farmer. The advocates of the St. Lawrence Ship Canal, permitting ocean liners to visit Chicago, Ill., Duluth, Minn., and other Lake ports, believe their waterway is the best solution of the transportation troubles and advocate its completion jointly by the American and Canadian Governments. Those who favor the improvement of the Mississippi River System of Waterways are equally sure that the export wheat should find exit *via* the Gulf ports. Others see relief only in the improvement of rail transportation.

A study of the wheat map of the United States (Fig. 1), may aid in solving this problem. The great surplus wheat States lie on the eastern slope of the Rocky Mountains, and the wheat finds outlet through four main depots—St. Paul, Minn., Omaha, Nebr., Kansas City and St. Louis, Mo. Under the present rail freight structure, the cheapest route to the seaboard is to the south through the Gulf ports. Shippers realize this, as shown by the wheat export figures for the fiscal years ending June 30th, 1920 and 1921. The shipments are:

	1920.	1921.
Through Gulf Ports.....	97 000 000 bushels	160 000 000 bushels
Through Atlantic Ports..	79 000 000 "	92 000 000 "



and this in the face of poorer facilities and shortage of boats at the Gulf ports. The Eastern ports also have the advantage of Lake transportation during part of the season. The increase in shipments through the Gulf ports in 1921 results from increased freight rates and the better supply of boats at these ports.

In any study of economic wheat transportation, one must not lose sight of the under-production that exists in the eastern part of the United States. Turn, now, to the most economic method of supplying these needs. In export rates, St. Louis has the advantage over St. Paul of 10.2 cents per bushel through Gulf ports, and Kansas City enjoys an advantage of 4.8 cents through the same ports. For domestic trade, St. Louis has an advantage over St. Paul

in the New York markets of 12.3 cents per bushel (not shown on Fig. 1), but Kansas City and Omaha have an advantage of only 3 cents per bushel. St. Louis cannot supply the needs. Manifestly, the wheat should come from the St. Paul District, which it does very largely. Moreover, St. Paul is favored with a partial water route *via* the Great Lakes, and, in 1920, there was carried through the "Soo" Canal approximately the northern surplus shown in the Northern States of Montana, North and South Dakota, and Minnesota. Part of the "Soo" traffic, of course, was Canadian wheat. Flour shipped through the "Soo" Canals is annually about sufficient to supply the New York State shortage.

Next, in order, the shortage in the Southern States must be supplied. This can best be done by drawing on the surplus from Nebraska, Iowa, Illinois, Missouri, and Kansas, as shown. These States actually do supply much of this deficiency. This leaves, as exportable, surplus wheat grown in Wyoming, Colorado, Kansas, and Oklahoma, and the extreme Northwest, which properly finds exit as shown. So much for existing conditions. How shall we set out to improve them?

First, let us consider supplying the domestic trade. Reference to the map (Fig. 1), will show that the great deficiency exists in the Northeastern States. The domestic rail rate from St. Paul to New York is 36 cents per bushel, while the domestic rate from St. Louis to New York is 23.7 cents per bushel, giving St. Louis an advantage of 12.3 cents per bushel. This advantage can be more than offset by a greater use of the waterways now available. Large quantities of wheat and flour are transported annually over the Great Lakes from Duluth, Minn., to Buffalo, N. Y. The quantity of flour passing through the "Soo" Canal annually is sufficient to supply the deficiency in New York State. Now that the New York State Barge Canals are completed, shippers should avail themselves of this waterway to distribute wheat and flour from Buffalo eastward. The normal charge for transporting wheat from Duluth to Buffalo is 2 cents per bushel. At the present time, wheat is sent from Chicago to Buffalo at from 1¾ to 2 cents per bushel. In pre-war days, flour was shipped from Duluth to Buffalo for the equivalent of about 4 cents per bushel of wheat. In 1920, the rate was 6 cents per bushel. Wheat and flour from the North Central States would reach Duluth by rail at approximately 10 cents per bushel. This would permit shippers to deliver wheat and flour in Buffalo at rates of from 12 to possibly 15 cents per bushel. After it has reached Buffalo, it is in the territory of deficiency, and can be delivered by rail and water from that point. By an intelligent use of the existing waterways on the northern border of the United States, it is quite possible that a rate of 16 cents per bushel can be maintained from the St. Paul District to New York City, which would show an advantage over the St. Louis all-rail rate of approximately 8 cents per bushel. Navigation through the "Soo" Canal is carried on over a period of about 8 months per year. In order to secure the advantages of water transportation throughout the year, it would be necessary, therefore, to supply storage for a four months' consumption of wheat and flour.

Export Rate
Export Rate
Export Rate

The most feasible means for relief to the Southeastern States is by a more extended use of the rivers of the Mississippi Valley. Wheat and flour can be collected at the important grain and flour centers such as St. Paul, Kansas City, and St. Louis, floated down the Mississippi and Missouri Rivers, and up the Ohio, Tennessee, Cumberland, Warrior, and other streams, to points of consumption. The Federal Government maintains a boat line between New Orleans, La., and St. Louis, which now quotes rates 20% below the rail rates. With the new equipment in use on this line during this season, it is reported that a very handsome profit is being earned at these rates. Great improvement can be realized by the construction of adequate terminals and transhipping facilities at various points along the river. Without doubt, if these streams are properly improved and facilities for handling commodities provided equal to that found on the railroads, water rates can be maintained at as low as one-half the rail rates, and probably much below these figures when quantity shipments are made.

Several schemes have been advanced for the improvement of shipping facilities for the export trade. The destination of export wheat is shown on the wheat map, Fig. 1. It will be noted that the great bulk of the export wheat is consumed in European countries. The North Atlantic cities, including Montreal, have an advantage over New Orleans in distance to London and Continental European ports of approximately 1 500 miles. Montreal has a slight advantage over New York in distance to Liverpool, but owing to the more dangerous route down the St. Lawrence River from Montreal, and to the further fact that Montreal is only a seven months' port, New York has the advantage to all European ports. To compensate for the greater distance to Europe, the rates which shippers are now charging from Gulf ports, are from 1½ to 3 cents per bushel more than from North Atlantic points, or an average of about 2 cents per bushel. The export rail rate from St. Paul, Omaha, Kansas City, and St. Louis, through the Gulf ports, is from 5 to 7 cents per bushel less than through the North Atlantic ports. The net result, therefore, is that the Gulf ports have an advantage of from 3 to 5 cents per bushel in shipments to Europe. This advantage is reflected in the increased use of the Gulf ports. The advocates of the St. Lawrence Ship Canal argue that this advantage can be more than overcome if ocean liners can reach Chicago and Duluth. It has been shown previously that all the north central surplus is required for domestic deficiency in the East Central States. This would leave as the only surplus that from such States as Nebraska and Kansas, to be sent by water from Chicago to European points. The local rail rate from Omaha and Kansas City to Chicago is 16½ cents per bushel. After it reaches Chicago, the wheat is still nearly 1 500 miles from tide-water and more than that distance when measured in time of navigation through open water. In order to reach tide-water, it must pass through the new Welland Canal and through the improved St. Lawrence River, passing possibly sixteen locks in all before it reaches Montreal. With a normal rate of 2 cents per bushel from Chicago to Buffalo, it is probable that a rate of at least 3½ cents per bushel would be required to deliver the wheat from Chicago to Montreal or, say, 20 cents per bushel from Omaha and Kansas City to the seaboard. This

would give an apparent advantage over the Gulf ports of a total of 5 cents per bushel—2 cents in ocean haul and 3 cents in rail haul from Omaha and Kansas City to the Gulf ports. This advantage is apparent only. Wheat is not raised in Omaha and Kansas City, but at a great distance westward from these points, which distance does not add materially to the distance to Gulf ports, whereas, it must be added to any movement east through Chicago. Therefore, even with the construction of the St. Lawrence Ship Canal, it is probable that Nebraska and Kansas wheat would find its way south through Galveston and would not all be collected in Omaha and Kansas City, but at such points as Lincoln, Nebr., Topeka, Kans., Wichita, Kans., and other centers in Central and Western Nebraska and Kansas. It must be remembered that distance from Chicago to Continental Europe by water, *via* the St. Lawrence River, is approximately the same as from the Gulf ports to Continental Europe, and the time of passage through the northern route is greater, with more hazards to navigation. Moreover, the northern route is only a seven months' channel, whereas, the southern route is open throughout the year. There is, therefore, a distinct advantage in shipping export grain *via* the southern route.

In order to lower the cost of haul on export grain from Nebraska, Kansas, and Oklahoma, we must either improve rail facilities or make the Mississippi and Missouri Rivers navigable for fleets of large tonnage. There appears to be little chance of lowering the rail rate, although there is a strenuous effort being made now by agricultural interests to that end. The railroad managers are now arguing that any reduction in rates on wheat must be compensated for by additional rates on other commodities. The Rock Island Railroad estimates that if the rail rate on wheat alone is lowered 20%, the loss to that road will be $5 000 000 annually. It will be seen, therefore, that any reduction in the rail rate is simply a shifting of the burden from one commodity to another. Wheat can be floated down the Missouri and Mississippi Rivers at rates far below the existing rail rates and, with a proper development of these streams, a rate at least as low as one-half the present rail rate can be maintained with profit. This would show a saving in cost of haul from Kansas City of approximately 12 cents per bushel. In other words, a water rate could probably be maintained as low as the pre-war rail rate and, with a return to normal conditions, this rate could be still further reduced. There is an increasing demand for mill products for feed to live stock grown in the Central West. The rates should be regulated so as to encourage the grinding of wheat at Omaha, Kansas City, and St. Louis, retaining the mill product for stock purposes and shipping the finished product—flour—abroad.

Viewing the situation as shown from the wheat map (Fig. 1), there does not seem to be any excuse for any export wheat from the Central West crossing the Mississippi River. The rivers should be improved so as to accommodate craft of large tonnage and shallow draft, and terminals, elevators, and flour mills should be developed along the streams to collect and grind this wheat and float it down to New Orleans.

In addition to the saving in cost of haul, the much congested Port of New York would be relieved. The New York foreign commerce is now

approximately 50% of the total foreign commerce of the United States. The congestion is so great as to add materially to the cost of haul. In the natural growth of the country, this congestion will increase, but no matter how great the facilities for added piers and terminals at the port, the collection of this great tonnage is bound to cause congestion, delays in transportation, and added interest on goods in transit.

The conclusions reached from this argument are:

1.—The producers and consumers of the United States have an added burden of $100 000 000 annually on transportation of wheat due to increased rail rates since 1914.

2.—The main economic route and destination of the surplus wheat of the North Central States is *via* the Great Lakes to Buffalo, thence by rail and water to the North Atlantic States.

3.—The South Atlantic and Gulf States, where deficiency occurs, should be supplied from the Central Mississippi Valley States *via* rail and water.

4.—European, African, South American, and Central American export wheat should come from the Central and South Mississippi Valley States and should be shipped *via* rail and water to Gulf ports.

5.—Additional milling facilities should be provided at Omaha, Kansas City, and St. Louis.

6.—The streams of the Mississippi Valley should be improved to afford an adequate navigable channel for the collection and distribution of wheat and other commodities.

7.—Modern terminals along these streams should be provided both for collection and distribution.

8.—Much may be said in favor of the proposed St. Lawrence Ship Canal, but it does not seem that its completion will materially benefit the surplus wheat raisers of America.

The St. Lawrence Ship Canal has many things to commend it, and probably it should be constructed for its general benefit to commerce and for the power that may be developed along its course; but relief to the farmers must be reached through the Southern route.

NELSON P. LEWIS,* M. AM. SOC. C. E.—The speaker has heard with great interest what has been said on this subject, and the freedom and frankness of the discussion has appealed to him. It is well for Americans to know what their Canadian neighbors are doing, and it is well to hear a protest against over-centralization and a plea for the smaller ports.

Some hysterical complaints have been heard that the Port of New York is losing its prestige by reason of the fact that the percentage of the foreign commerce of the United States, handled through the Port of New York, has greatly decreased during the last generation or two. It is quite natural that this should be so in view of the development of other parts of the country with seaports located so as to avoid excessive hauls by rail. Had not new commercial ports been developed and had New York's percentage of the country's total commerce been maintained, the congestion due to over-centralization

* Cons. Engr., New York City.

would have been unwholesome and unfortunate. New York Harbor has such great natural advantages that if the port is intelligently organized and adequate facilities are provided, it will retain all the commerce to which it is entitled, and it need not worry about the development of other ports, whether large or small. There is needed in New York a broader conception of the whole problem and an avoidance of provincialism.

T. Howard Barnes,* M. Am. Soc. C. E.—One of the special topics of this discussion, namely, the relation of warehouses to port development, is timely and should be taken up more at length.

The relation is so intimate and the people are so accustomed to having a warehouse of some capacity connected with the quays and piers that they do not stop to analyze the relation of a part to the whole. This relation has been alluded to by several of the speakers, one of whom noted briefly the economy obtained where ample warehouses were so provided. The remarkable economy per linear foot of pier in certain cities has also been mentioned without a full analysis of the reasons therefor. The question is, to what extent is such economy attributable to warehousing facilities on or at the pier?

The American system, or it might be called the primitive system, of building piers is the putting up of a structure for the quick landing of materials with a minimum of concern, at the time, beyond that of getting such materials unloaded and transferred to the shore. Even now such practice may be noted in less developed regions, and it cannot be wholly condemned in view of the uncertainty of what the future will demand. Many times, however, these developments have grown up "Topsy-like" without sufficient regard for future plans, and, thus, the opportunity for making efficient use of the original structure is forfeited.

Perhaps, the best examples of this practice are the old piers lining the North and East Rivers in New York City. At the time the earlier of these were built, there was no great reason for a storage shed more than one story in height to receive the small cargo. Congestion on Manhattan Island was not the serious question it is to-day. Trucks could come and go without the present-day delays, and near-by warehouses for storage were obtainable. To-day, all this is changed, and the speaker believes that it is an economic crime to permit the erection of piers having warehouses less than three or four stories in height.

An example of the efficiency obtained by providing ample wharf shed was illustrated a few years ago in the extension of a pier in a tropical port, which was under the speaker's charge. A large part of the imports for the interior were brought over this pier. Such imports had always been discharged on to cars, switched into the Custom House on shore, and there unloaded and sorted. The new construction provided for ample floor space on the pier, the roofed area being made level with the platform of the cars. The shed structure was provided with doors at all points by which the cargo could be received as fast as the ship's sling could handle it. The time of discharging was cut substantially in two, likewise the expense of handling on shore,

* Cons. Engr., New York City.

resulting not only in economy of handling cost, but in a very considerable saving in breakage.

All this argues in favor of having a clear space within which to receive the ship's cargo, and it must be remembered that a proper ship's tackle with plenty of winches is an effective way of discharging cargo. It must be borne in mind also that delays in discharging have been due more to a lack of opportunity to keep the cargo moving after it has been lifted out than from the fact that the ship's sling is inadequate, and that overhead cranes or other apparatus might be the remedy.

Once the cargo is landed on shore, the flow must be provided for in accordance with the demands, and it is at this stage that cranes and gantries excel. In the crowded situation in New York City, the possibility of warehousing the lighter portion, at least, in the upper stories, the convenience which this storage means to the importer, and the advantage which it affords the ship owners in accumulating cargo for export purposes, all argue most strongly for provision for that "room at the top" which the multiple-story form of construction secures.

Paper No. 1483

THE CIRCULAR ARCH UNDER NORMAL LOADS

By William Cain,* M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Mensch, B. F. Jakobsen, Fred A. Noetzli, and William Cain.

Synopsis

In the theory of curved dams, the deflection of a horizontal circular arch under normal loads plays an important rôle. The main object of the following investigation is to derive nearly exact formulas for this deflection, as well as formulas for moment, thrust, and shear, both for arches "fixed" (encastré) at the ends and for those free to turn or "hinged" at the abutments. Since the only approximation introduced consists in neglecting the influence of shear on the deformation, the results may be characterized as nearly exact.

It is left to the engineer's judgment to choose the results best adapted to the conditions at the abutments as actually constructed. For thin dams, the theory pertaining to "hinged ends" may be nearer the truth; for thick dams, the hypothesis of "fixed ends" may be more nearly realized. In case anchoring with steel bars to the side-hills is resorted to, the conditions there become more definite.

The formulas being necessarily long, a number of tables of numerical coefficients have been prepared to aid in a quick computation of deflections, or for use where deflections are given by observation and stresses are to be ascertained.

In the analysis of arched dams, the dam is supposed to be divided into a series of horizontal arches, each 1 ft. in depth, and free to move over each other,† and the solution is based on the principle that the deflection of any arch and of the corresponding vertical cantilever at its crown, must be the same. The part of the normal load borne by each arch in turn is thus ascer-

* Prof. of Math., Univ. of North Carolina, Chapel Hill, N. C.

† On this point, see the writer's discussion of the paper entitled "Gravity and Arch Action in Curved Dams", by Fred A. Noetzli, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 71.

tained; and it is this load, acting in a radial direction, that figures in all the computations that follow.

Very simple formulas for the deflection of a horizontal arch subjected to normal loads, have been derived by B. A. Smith, M. Am. Soc. C. E.,* and by F. A. Noetzli, Assoc. M. Am. Soc. C. E.†

Using the notation given in connection with Fig. 1, the crown deflection η, can be reduced to the forms:

$$\text{(Smith)}, \quad \eta = \frac{3}{2} \frac{p' r'^2}{E t},$$

$$\text{(Noetzli)}, \quad \eta = 1.56 \frac{p' r r'}{E t}.$$

These formulas were derived, for arches "hinged at the ends", by considering the deformations due only to the circumferential thrust, the influence of bending moments being neglected. They are, consequently, only approximate.

In Table 1 are given the numerical coefficients corresponding to the (nearly) exact solutions of Equations (15) and (19). By comparison, it is seen that the coefficient, 1.56, of Mr. Noetzli's formula, is sufficiently near for thin dams with "hinged ends" for the usual central angles; but for thick dams and small central angles, the approximate solution gives very erroneous results. The differences are still more pronounced when the arch is really "fixed at the ends."

TABLE 1.—CIRCULAR ARCH FIXED AT ENDS, UNDER NORMAL LOADS.

180°	1.637	1.636	1.635	1.634	1.632	1.630	1.627

For the latter case, the late R. Shirreffs, M. Am. Soc. C. E.‡ derived an approximate formula for deflection which is as complicated as the (nearly)

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 2027.

† *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

‡ *Transactions*, Am. Soc. C. E., Vol. LIII (December, 1904), pp. 163–166.

exact formula, Equation (15), and differs from it in its results very materially, so that it should be rejected.

In the ordinary theory, where vertical loads only are considered, the influence of moment and thrust can be separately considered; but, for the uniform normal loads, the investigation that follows will show that this separation is inadmissible, since it gives $M = 0$, throughout. Mr. Shirreffs, in his analysis, attempts this separation and likewise ignores the influence of P on bending, and the compression of the arch due to H', which is really the equivalent of $(p\,r - P_0)$, as given later. These considerations will sufficiently account for the difference in the results mentioned.

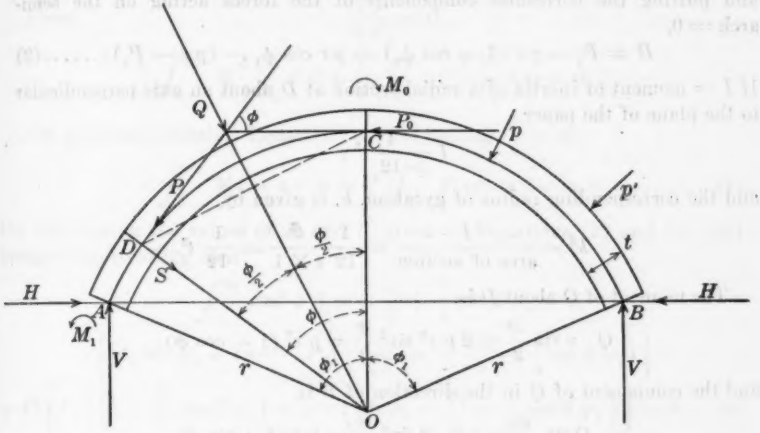

FIG. 1.

CIRCULAR ARCH OF UNIFORM RADIAL THICKNESS, FIXED AT THE ENDS AND SUBJECTED TO A UNIFORM NORMAL RADIAL PRESSURE.

Fig. 1 is supposed to represent a horizontal circular arch, 1 ft. thick perpendicular to the plane of the paper.

Let, t = uniform radial thickness of arch, in feet;

r = radius of center line of arch, in feet;

r' = radius of extrados, in feet;

p' = normal radial pressure, in pounds per square foot, on extrados;

p = normal pressure, in pounds per square foot, on center line $= \dfrac{p'\,r'}{r}$;

ϕ = angle with radius of crown for any point, D;

ϕ_1 = half central angle, $A\,O\,B$;

s = length of arc, $C\,D = r\phi \therefore ds = r\,d\phi$;

E = modulus of elasticity of arch, in pounds per square foot;

M_0 = moment at crown, taken positive clockwise;

P_0 = thrust at crown;

M, P, and S are, respectively, the moment, tangential component of the thrust, and shear at D (r, ϕ).

From symmetry, the thrust, P_0, at the crown, is normal to the radial section there and the shear is zero. At the left abutment, the components of the reaction parallel and perpendicular to $O\,C$ are V and H, and the reaction moment is M_1. These forces V, H, M_1, with P_0, M_0, and the load on the semi-arch, hold the latter in equilibrium, so that it can be treated as a free body.

By Merriman's "Hydraulics",* the component, Q, of the loads on the arch segment, $C\,D$, acting perpendicular to the plane, $C\,D = p\,.\,C\,D = p\,.\,2\,r\sin\frac{\phi}{2}$. Similarly,

$$V = p\,r\sin\phi_1 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and putting the horizontal components of the forces acting on the semi-arch $= 0$,

$$H = P_0 - p\,r\,(1 - \cos\phi_1) = p\,r\cos\phi_1 - (p\,r - P_0) \ldots\ldots (2)$$

If I = moment of inertia of a radial section at D about an axis perpendicular to the plane of the paper

$$I = \frac{1}{12}\,t^3\,;$$

and the corresponding radius of gyration, k, is given by,

$$k^2 = \frac{I}{\text{area of section}} = \frac{1}{12}\,\frac{t^3}{t \times 1} = \frac{1}{12}\,t^2.$$

The moment of Q about D is,

$$Q\,.\,r\sin\frac{\phi}{2} = 2\,p\,r^2\sin^2\frac{\phi}{2} = p\,r^2\,(1 - \cos\phi).$$

and the component of Q in the direction of P is,

$$Q\sin\frac{\phi}{2} = p\,r\,.\,2\sin^2\frac{\phi}{2} = p\,r\,(1 - \cos\phi).$$

On taking moments of the forces acting from C to D about D,

$$M = M_0 + (p\,r - P_0)\,r\,(1 - \cos\phi) \ldots\ldots\ldots\ldots\ldots (3)$$

Also, since P equals the sum of the components of P_0 and Q parallel to P,

$$P = P_0\cos\phi + p\,r\,(1 - \cos\phi) = p\,r - (p\,r - P_0)\cos\phi \ldots\ldots (4)$$

Taking partial derivations of Equations (3) and (4),

$$\frac{\delta M}{\delta M_0} = 1,\ \frac{\delta M}{\delta P_0} = -\,r\,(1 - \cos\phi);\ \frac{\delta P}{\delta M_0} = 0,\ \frac{\delta P}{\delta P_0} = \cos\phi.$$

The internal elastic work, L, of the semi-arch, neglecting that due to shear as inappreciable, is

$$L = \frac{r}{2}\int_0^{\phi_1}\frac{M^2\,d\,\phi}{E\,I} + \frac{r}{2}\int_0^{\phi_1}\frac{P^2\,d\,\phi}{E\,t} \ldots\ldots\ldots\ldots\ldots (5)$$

By the theorem of Castigliano,† the values of the unknowns, M_0, P_0, can be found by putting $\frac{\delta L}{\delta M_0} = 0$, $\frac{\delta L}{\delta P_0} = 0$ and solving.

* Eighth Edition, p. 35.
† "Systèmes Elastiques", p. 265.

From $$\frac{\delta L}{\delta M_0} = 0,$$

$$\frac{r}{EI}\int_0^{\phi_1} M \frac{\delta M}{\delta M_0} d\phi = 0,$$

therefore,

$$\int_0^{\phi_1} M \, d\phi = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

By aid of Equation (3), this reduces to

$$M_0 \phi_1 + (pr - P_0) r (\phi_1 - \sin \phi_1) = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (7)$$

From $$\frac{\delta L}{\delta P_0} = 0,$$

$$\frac{1}{I}\int_0^{\phi_1} M \frac{\delta M}{\delta P_0} d\phi + \frac{1}{t}\int_0^{\phi_1} P \frac{\delta P}{\delta P_0} d\phi = 0,$$

On reducing, utilizing Equation (6), and putting $\frac{I}{t} = k^2$,

$$r\int_0^{\phi_1} M \cos\phi \, d\phi + k^2 \int_0^{\phi_1} P \cos\phi \, d\phi = 0 \quad \ldots\ldots\ldots\ldots (8)$$

On substituting the values of M and P, given by Equations (3) and (4), and integrating, recalling that

$$\int_0^{\phi_1} \cos^2\phi \, d\phi = \frac{\phi_1}{2} + \frac{1}{4}\sin 2\phi_1,$$

$$r\left[M_0 \sin\phi_1 + (pr - P_0) r \left(\sin\phi_1 - \frac{\phi_1}{2} - \frac{1}{4}\sin 2\phi_1\right)\right]$$

$$+ k^2\left[P_0\left(\frac{\phi_1}{2} + \frac{1}{4}\sin 2\phi_1\right) + pr\left(\sin\phi_1 - \frac{\phi_1}{2} - \frac{1}{4}\sin 2\phi_1\right)\right] = 0 \quad \ldots\ldots (9)$$

To eliminate M_0, multiply Equation (7) by $r \sin\phi$, and Equation (9) by ϕ_1, subtract the last equation from the first, multiply by $\frac{2}{r^2}$, and solve for $(pr - P_0)$,

$$(pr - P_0) = \frac{pr}{D} 2\phi_1 \sin\phi_1 \frac{k^2}{r^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

where

$$D = \left(1 + \frac{k^2}{r^2}\right)\phi_1\left(\phi_1 + \frac{1}{2}\sin 2\phi_1\right) - 2\sin^2\phi_1 \quad \ldots\ldots\ldots (11)$$

From Equation (10), P_0 can be at once derived. From Equation (7),

$$M_0 = -(pr - P_0) r \left(1 - \frac{\sin\phi_1}{\phi_1}\right) \quad \ldots\ldots\ldots\ldots\ldots (12)$$

which gives M_0 when $(pr - P_0)$ has been computed from Equation (10). Similarly, from Equations (1) and (2), the components of the reaction at the abutment are ascertained.

If Equation (12) is substituted in Equation (3), we find,

$$M = r(pr - P_0)\left(\frac{\sin\phi_1}{\phi_1} - \cos\phi\right) \quad \ldots\ldots\ldots\ldots\ldots (13)$$

giving the moment at any point, D (r, ϕ). The value of P there is given by Equation (4).

The shear, S, on the radial section at D will be taken as positive when directed toward the center. The load on the segment, CD, of the arch, due to the normal pressures, p, contributes to this shear a component parallel to $D\,O = p\,r \sin \phi$.* The component of P_0 parallel to $D\,O = -P_0 \sin \phi$; whence

$$S = (p\,r - P_0) \sin \phi \qquad (14)$$

It will be observed from Equations (4), (12), (13), and (14), how persistently the factor $(p\,r - P_0)$ appears; hence, in a numerical example, it is advisable to begin by computing $(p\,r - P_0)$ from Equation (10); whence P_0 can be found, and from Equations (12), (13), (4), and (14), the values of M_0, M, P, and S can then be evaluated. Table 2 (given under "Temperature Stresses"), will prove an aid in the computation of $(p\,r - P_0)$.

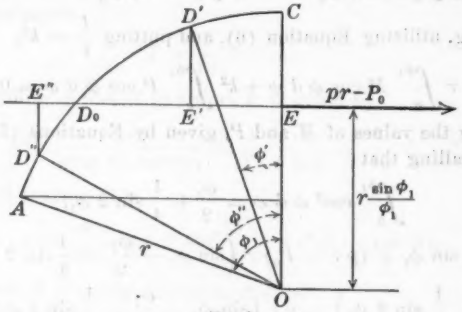

FIG. 2.

The expression for M can be put in a simpler form. In Fig. 2, lay off $(p\,r - P_0)$ as a force acting to the right, perpendicular to the crown radius, $O\,C$, and at a distance $O\,E$ from O equal to $r\,\frac{\sin \phi_1}{\phi_1}$, the length (as shown in Mechanics) of the ordinate to the center of gravity of the arc, $A\,C$. Then, from Equation (13), we have,

$$M = (p\,r - P_0)\left(r\,\frac{\sin \phi_1}{\phi_1} - r \cos \phi\right) = (p\,r - P_0)\,(O\,E - r \cos \phi)\,;$$

therefore, for $\phi = \phi'$, or point D',

$$M = -(p\,r - P_0)\,E'\,D'\,;$$

whereas for D'' $(\phi = \phi'')$,

$$M = +(p\,r - P_0)\,D''\,E''.$$

At D_0, where the force line $(pr - P_0)$ meets the arc, $A\,C$, $M = 0$; for points between D_0 and C, M is negative, and decreases numerically in going from C to D_0; for points between D_0 and A, M is positive and increases from zero at D_0 to a maximum at A. From a large scale drawing, the values of $E'\,D'$ and $E''\,D''$ can be scaled off and the values of M quickly computed.

* On the principle (Merriman's "Hydraulics," 8th ed., p. 35) that the component of this load on CD in any direction, equals p times the projection of CD on the perpendicular to this direction, or $p \times r \sin \phi$.

By the theory of the arch, the radial distance from the center of any section, as D', to the center of pressure on that section is equal to $\frac{M}{P}$; hence, since clockwise moments were taken as positive, the line of the centers of pressure meets the crown section on the extrados side of the center line of the arch; it then gradually approaches the center line in going from C to D_0 (Fig. 2); at D_0, it crosses the center line, and from D_0 to A_1, it recedes from it increasingly, lying now on the intrados side, and attains its maximum departure from the center line at A. It is true, from Equation (4), that P increases gradually, in going from the crown to the abutment, but not sufficiently so to invalidate the conclusion, as the following numerical illustrations will show:

1.—Let $t = 4$ ft., $r = 135$ ft., and $\phi_1 = 60°$; then, at the crown, $P_0 = 0.99735\, p\, r$, and $M_0 = -0.061965\, p\, r$; whence, $\frac{M_0}{P_0} = -0.0621$ ft., or the center of pressure at the crown is about 0.06 ft. from the center.

2.—Let $t = 40$ ft., $r = 135$ ft., $\phi_1 = 20°$; then $P_0 = 0.024818\, p\, r$, and $M_0 = -2.657282\, p\, r$; whence, $\frac{M_0}{P_0} = -107.07$ ft., or the center of pressure is 107 ft. from the center of the crown section on the extrados side.

In the first example, the thrust, P_0, is nearly $p\, r$, as given by the cylinder formula; whereas, in the second example, P_0 is only about $2\frac{1}{2}\%$ of $p\, r$. It is evident from this how erroneous it would be to assume the cylinder formula for thick arches. In this second example, the arch action is very small, so that the arch acts nearly as a beam fixed at the ends.

The shear, S, as given by Equation (14), is always positive, or directed toward the center. It is zero at the crown ($\phi = 0$), and attains a maximum at the abutment ($\phi = \phi_1$). Consequently, the thrust, $\sqrt{P^2 + S^2}$, on any radial section is not normal to that section, save at the crown, and its component, S, is directed toward the center. The unit stress at extrados or intrados is given by the usual formulas and diagrams, according as the arch is reinforced or non-reinforced.

For brevity, let the symbol $\doteq$ denote "approaches indefinitely" (as a limit); then from Equations (10) and (12), it is seen that as $t \doteq 0$ (and therefore $k \doteq 0$), $p\, r - P_0 \doteq 0$, or $P_0 \doteq p\, r$ and $M_0 \doteq 0$. Also, from Equations (3) and (4), as $t \doteq 0$, $M \doteq 0$ and $P \doteq p\, r$, the "cylinder formula."

The elastic work due to the axial components, P, is given by the term in P in Equation (5), and its influence in the term involving k^2 in Equation (8) and the following equations; hence, at first glance, it would seem that the effect due to M alone could be found by putting $k = 0$ throughout; but, as shown, this gives $P = p\, r$, $M = 0$ throughout, which is absurd. Thus, the effect of M and P cannot be separated, as is done in the ordinary theory, where vertical loads alone are considered. It appears then, that only a theory like the foregoing, which includes the influence of both M and P throughout, can be expected to effect a solution; and it is on that account, mainly, that Mr. Shirreffs' ingenious solution, already referred to, fails to give reliable results.

Radial Deflection at the Crown, Fixed Ends.

In the case of the arch, Fig. 1, "fixed at the ends", let a small additional load, w, acting in the direction, $C\ O$, be supposed to be applied to the left half arch at the crown. Designating by M' and P', the new moment and thrust at D, we have only to add to M and P, as given by Equations (3) and (4), the proper terms in w. Therefore,

$$M' = M + w\,r \sin \phi \therefore \frac{\delta M'}{\delta w} = r \sin \phi,$$

$$P' = P + w \sin \phi \therefore \frac{\delta P'}{\delta w} = \sin \phi$$

As before, the left half arch is treated as a cantilever, and it is supposed to be in equilibrium under the action of the load, w, the couple the moment of which is M'_0, and the thrust P'_0—all acting at the crown—the loads, p, and the consequent reactions at the left abutment.

The elastic internal work of deformation of the cantilever is,

$$L' = \frac{r}{2}\int_0^{\phi_1} \frac{M'^2}{E\,I}\,d\,\phi + \frac{r}{2}\int_0^{\phi_1} \frac{P'^2}{E\,t}\,d\,\phi$$

Therefore, by Castigliano's theorem,* the deflection, η, at the crown, in the direction, CO, is to be found by taking the partial derivative of L' with respect to w and then putting $w = 0$ in the expressions for M' and P', thus reducing them to M and P. Therefore,

$$\eta = \frac{r}{E\,I}\int_0^{\phi_1} M \frac{\delta M'}{\delta w}\,d\,\phi + \frac{r}{E\,t}\int_0^{\phi_1} P \frac{\delta P'}{\delta w}\,d\,\phi$$

$$\frac{E\,I}{r}\,\eta = \int_0^{\phi_1} M\,r \sin \phi\,d\,\phi + k^2 \int_0^{\phi_1} P \sin \phi\,d\,\phi$$

On substituting the values of M and P given by Equations (13) and (4), and integrating, we find,

$$\frac{E\,I}{r}\,\eta = r^2\,(p\,r - P_0)\left[\frac{\sin \phi_1}{\phi_1}(1 - \cos \phi_1) - \frac{1}{2}\left(1 + \frac{k^2}{r^2}\right)\sin^2 \phi_1\right] + k^2\,p\,r\,(1 - \cos \phi_1).$$

On substituting the value of $(p\,r - P_0)$ given by Equation (10), and writing,

$$\sin^2 \phi_1 = 1 - \cos^2 \phi_1 = (1 + \cos \phi_1)(1 - \cos \phi_1),$$

$$\frac{E\,I}{r}\,\eta = p\,r\,k^2\,(1 - \cos \phi_1)\,\frac{1}{D}\left[2 \sin^2 \phi_1 - \left(1 + \frac{k^2}{r^2}\right)\phi_1 \sin \phi_1\,(1 + \cos \phi_1) + D\right].$$

On substituting the value of D given by Equation (11), the last bracket reduces to,

$$\left(1 + \frac{k^2}{r^2}\right)\phi_1\,(\phi_1 - \sin \phi_1),$$

* "Systèmes Elastiques", p. 27 or p. 265.

so that, finally, on solving for η, we find, after putting $2 \sin^2 \phi_1 = 1 - \cos 2\phi_1$, $\frac{k^2}{I} = \frac{1}{t}$, and dividing numerator and denominator by $\left(1 + \frac{k^2}{r^2}\right) \phi_1$,

$$\eta = \frac{p}{E} \frac{r^2}{t} \frac{(\phi_1 - \sin \phi_1)(1 - \cos \phi_1)}{\left(\phi_1 + \frac{1}{2} \sin 2\phi_1\right) - \frac{1 - \cos 2\phi_1}{\phi_1 \left(1 + \frac{k^2}{r^2}\right)}} \quad \ldots\ldots\ldots\ldots (15)$$

The coefficients, c, of $\frac{p}{E} \frac{r^2}{t} \left(= \frac{p'}{E} \frac{r}{t} \frac{r'}{}\right)$, have been given in Table 1 for various values of $\frac{t}{r}$ and $2\phi_1$.

In applying this formula, if t and r are in feet and p in pounds per square foot, then E must be expressed in pounds per square foot (not inch). Also, ϕ_1 must be expressed in radians, corresponding to the angle as given in degrees, for which the trigonometric functions are found. Since, generally, $2\phi_1 > 90°$, use, $\sin 2\phi_1 = \sin (180° - 2\phi_1)$, $\cos 2\phi_1 = -\cos (180° - 2\phi_1)$. In numerical computations, such a logarithmic table must be used as to give, at least, three significant figures in the denominator. A 5-place table will usually suffice for $2\phi_1 > 90°$; but for smaller central angles, a 7-place table may be necessary. In fact, for $2\phi_1 = 20°$, an 8-place table was desirable.*

Since $\frac{k^2}{r^2} = \frac{1}{12} \left(\frac{t}{r}\right)^2$, the values of c in Table 1 remain the same, whatever the values of t and r, provided the ratio, $\frac{t}{r}$, remains unaltered. The factor $\left(1 + \frac{k^2}{r^2}\right)$ in Equation (15) can be written 1 for small values of $\frac{t}{r}$ when $2\phi_1 > 120°$, but this approximation would lead to large errors for small central angles. Thus, for $t = 4$, $r = 135$, $2\phi_1 = 20°$, the true value of c is 0.414; whereas, if $\left(1 + \frac{k^2}{r^2}\right)$ is replaced by 1 in Equation (15), the value of c resulting is 1.884. For large values of t $\left(\text{or of } \frac{t}{r}\right)$, the term in k must be retained throughout.

Circular Arch Hinged at Ends.

As before, the arch will be assumed to have a constant thickness, t, and to be subjected to normal loads, p' lb. per sq. ft. on the extrados, or $p = \frac{p'}{} \frac{r'}{r}$ lb. per sq. ft. along the center line of the arch. The center of the sections at the abutments will be regarded as fixed, but the sections there will be free to turn, or, technically, the arch will be "hinged at the ends." In addition to the previous notation, let (x, y) denote the co-ordinates of D

* An admirably arranged 8-place table is the one by Bauschinger and Peters. It is as convenient to use as a 7-place table.

with respect to A for an origin, x being perpendicular and y parallel to $O\,C$, the crown radius.

The Equations (1) to (5) pertaining to Fig. 1 apply equally to the case of hinged ends, Fig. 3.

Since $M = 0$ at the hinge, $\phi = \phi_1$. Therefore, from Equation (3),

$$M_0 = -(p\,r - P_0)\,r\,(1 - \cos\phi_1)$$

which reduces Equation (3) to,

$$M = -(p\,r - P_0)\,r\,(\cos\phi - \cos\phi_1) = -(p\,r - P_0)\,y \ldots\ldots (16)$$

The horizontal deflection of the crown is zero; whence $\frac{\delta L}{\delta P_0} = 0$, which gives the equation just below Equation (7), or,

$$\int_0^{\phi_1} M \frac{\delta M}{\delta P_0}\,d\phi + k^2 \int_0^{\phi_1} P \frac{\delta P}{\delta P_0}\,d\phi = 0 \ldots\ldots\ldots (17)$$

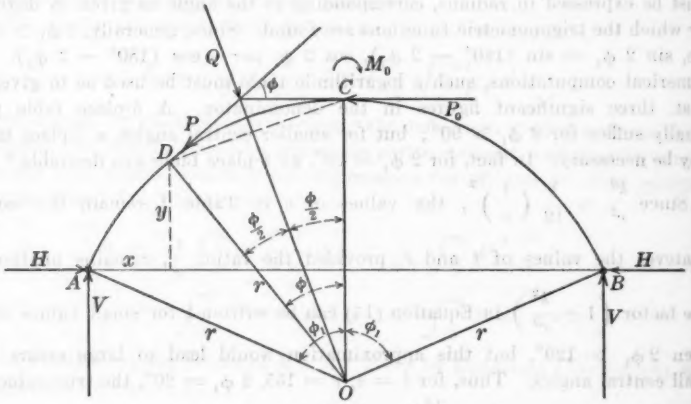

FIG. 3.

Substituting the values of the partial derivatives, integrating, and solving for $(p\,r - P_0)$, we find,

$$p\,r - P_0 = \frac{2\frac{k^2}{r^2}(p\,r)\sin\phi_1}{\phi_1\,(2 + \cos 2\,\phi_1) - \frac{3}{2}\sin 2\,\phi_1 + \frac{k^2}{r^2}\left(\phi_1 + \frac{1}{2}\sin 2\,\phi_1\right)} \ldots (18)$$

from which P_0 can be computed.

After $(p\,r - P_0)$ has been computed from Equation (18), the values of H, M, and P can be at once written down from Equations (2), (3), and (4).

Since $(p\,r - P_0)$ is always positive, by Equation (16), M is always negative, so that,

$$\frac{M}{P} = -\frac{(p\,r - P_0)\,y}{p\,r - (p\,r - P_0)\cos\phi},$$

is negative, or the line of the centers of pressure is everywhere on the extrados side of the center line of the arch ring except at the abutment,

where it passes through the center of the section. This line increases its distance from the arch axis in going from the abutment to the crown. This arch, with normal loading, is exceptional in that the line of the centers of pressure does not cross the arch axis. The result, however, is perfectly consistent with Equation (17), since the first integral in this equation is negative and the second positive, so that the algebraic sum can be zero.

It is very instructive to compare certain results pertaining, respectively, to thin and thick arches. Thus, let $r = 135$ ft., $2\phi_1 = 120$ degrees. Then, for $t = 4$ ft., previous formulas give $P_0 = 0.999534\ p\,r$; $M_0 = -0.03145\ p\,r$. Therefore,

$$\frac{M_0}{P_0} = -0.031 \text{ ft.};$$

whereas, for $t = 40$ ft., $2\phi_1 = 40°$, we find $P_0 = 0.2\ (p\,r)$; $M_0 = -54.0\ (p\,r)$. Therefore,

$$\frac{M_0}{P_0} = -270 \text{ ft.}$$

Thus, for $t = 4$ ft., P_0 is nearly equal to $p\,r$, and the center of pressure on the crown section is only 0.031 ft. from its center; whereas, for $t = 40$ ft., P_0 is only 20% of $p\,r$, and the center of pressure on the crown section extended is 270 ft. from the crown, on the extrados side.

It is plain from this that the use of the cylinder formula, $P = p\,r$, for thick arches, will lead to very erroneous results, not only for thrusts and moments, but also for deflections.

Radial Deflection at the Crown, Hinged Ends.

Taking the hinged point, A, Fig. 3, as fixed, regard the hinged end, B, as free to slide on a horizontal plane. Then, if a small radial load, w, is applied at the crown, the reactions due to it, at A and B, will be parallel to $O\,C$, and each will equal $\frac{w}{2}$. The horizontal thrust, H, acting from B toward A, can be supposed to be just sufficient to bring B back to its first position when $w = 0$. The arch is now in equilibrium under the normal loads, p, the reactions, V and H, at the hinged ends, the force, w, at C and the reactions, $\frac{w}{2}$, at A and B. Let M' and P' be the moment and tangential thrust at D corresponding.

The moment, M', at D of all forces and reactions to its right will equal the resisting moment of all forces and reactions on $A\,D$ in magnitude and sign provided the moments of right-handed couples of forces on $A\,D$ are taken as negative, since such moments on $D\,C$ were given the positive sign. Thus, the moment of $\frac{1}{2}\ w$ at A, about D, must be given the minus sign, so that $M' = M - \frac{1}{2}\ w\,x$, where M has the value given by Equation (16).*

* The formula for M was likewise directly proved by considering the forces acting on AD.

Similarly, the tangential component at D acting downward must equal the resisting component acting upward, therefore:

$$M' = M - \frac{1}{2} w x, \text{ and } \frac{\delta M'}{\delta w} = -\frac{1}{2} x = -\frac{1}{2} r (\sin \phi_1 - \sin \phi).$$

$$P' = P + \frac{1}{2} w \sin \phi, \frac{\delta P'}{\delta w} = \frac{1}{2} \sin \phi.$$

If U is the elastic work for the whole arch, then, neglecting the work of shear,

$$U = 2 \left[\frac{1}{2} \int_0^{\phi_1} \frac{M'^2}{E I} r \, d \phi + \frac{1}{2} \int_0^{\phi_1} \frac{P'^2}{E t} r \, d \phi \right];$$

whence the radial displacement, η, at the crown, as $w = 0$, is,

$$\eta = \frac{\delta U}{\delta w} = 2 \int_0^{\phi_1} \frac{M}{E I} \frac{\delta M'}{\delta w} r \, d \phi + 2 \int_0^{\phi_1} \frac{P}{E t} \frac{\delta P'}{\delta w} r \, d \phi.$$

On substituting the values of M and P given by Equations (16) and (4) and the values just given for the partial derivatives, we derive,

$$\frac{E I}{r^3} \eta = \int_0^{\phi_1} (P_0 - p r) (\cos \phi - \cos \phi_1) (\sin \phi - \sin \phi_1) \, d \phi$$

$$+ \frac{k^2}{r^2} \int_0^{\phi_1} \left[(P_0 - p r) \sin \phi \cos \phi + p r \sin \phi \right] d \phi$$

$$= (P_0 - p r) \left[\cos \phi_1 (\cos \phi_1 - 1) - \frac{1}{2} \sin^2 \phi_1 + \phi_1 \sin \phi_1 \cos \phi_1 \right.$$

$$\left. + \frac{k^2}{r^2} \frac{\sin^2 \phi_1}{2} \right] - \frac{k^2}{r^2} p r (\cos \phi_1 - 1).$$

The value of $(P_0 - p r)$, as given by Equation (18), is now substituted; after which considerable trigonometric and algebraic reduction* finally leads to the following formula for deflection:

$$\eta = p r^2 \frac{1 - \cos \phi_1}{E t B} \left[\sin \phi_1 + \phi_1 (1 - 2 \cos \phi_1) + \frac{k^2}{r^2} (\phi_1 - \sin \phi_1) \right]. \quad (19)$$

where

$$B = \phi_1 (2 + \cos 2 \phi_1) - \frac{3}{2} \sin 2 \phi_1 + \frac{k^2}{r^2} \left(\phi_1 + \frac{1}{2} \sin 2 \phi_1 \right).$$

Writing this in the form, $\eta = c \frac{p r^2}{E t} = c \frac{p' r r'}{E t}$, the coefficients, c, can be computed for varying values of $2 \phi_1$ (the central angle) and $\frac{t}{r}$. The results are given in Table 1 and have previously been discussed in connection with those pertaining to certain approximate solutions. The general remarks under Equation (15) apply equally here as to ensuring accuracy in the computations.

* The following formulas were used: $\sin 2 \phi_1 = 2 \sin \phi_1 \cos \phi_1$, $2 \cos^2 \phi_1 = 1 + \cos 2 \phi_1$, $\sin^2 \phi_1 = (1 + \cos \phi_1) (1 - \cos \phi_1)$. The factor $(1 - \cos \phi_1)$ will be found to be common to the terms in the numerator and can be taken out.

In the theory of curved dams, as given by Mr. B. A. Smith,* the formula for arch deflection involves a constant coefficient, c, so that an average value for the horizontal arches of varying thickness, for the entire height of the dam, will have to be used. This can be taken with sufficient accuracy, for thin dams, from Table 1. For very high dams, in which the thickness near the base is considerable, the coefficients may vary too much to effect a practical solution by use of an average coefficient. For thin dams, the solution is very satisfactory, and it can be effected, not only where the base of the dam is fixed, but likewise where it is simply supported on the foundation. Mr. Noetzli's tentative method† applies only to the case where the dam is fixed at the base. For this case, an average value of c can be used for thin dams; but for very high dams, the values of c corresponding to the varying values of the thickness, t, should be used. To save labor, a graph of the values of c for different heights, should be made. The solution can then be effected by proceeding along the lines indicated by the writer in his discussion‡ of Mr. Noetzli's paper, either for water loads or for temperature changes; the final test being that the deflections of the supposed horizontal arches and the vertical cantilever, at the crown of the arches, shall be the same at the same depth. The solution gives the values of p for any depth, from which moments, thrusts, shears, and stresses at the intrados and extrados can be computed.

Temperature Stresses.

Arch Fixed at the Ends.—If e = expansion per foot for a rise of temperature of 1° Fahr.; then, for t_0 degrees rise for the circular arch above an assumed mean, the thrust, H, acting perpendicular to the crown radial section, is given by the formula,§

$$H = \frac{2 \sin \phi_1}{D_0} \cdot \frac{E\, I\, e\, t_0}{r^2}$$

where

$$D_0 = \left(\phi_1 + \frac{1}{2} \sin 2\, \phi_1\right) \left(1 + \frac{k^2}{r^2}\right) - \frac{1 - \cos 2\, \phi_1}{\phi_1}.$$

Note that D of Equation (11) equals $\phi_1\, D_0$.

The numerical values of $\frac{2 \sin \phi_1}{D_0}$, for various values of $2\, \phi_1$ and $\frac{t}{r}$, are given in Table 2.

The formula for the moment, M, at any point $(r\ \phi)$ of the axis, is

$$M = H\, r \left(\cos \phi - \frac{\sin \phi_1}{\phi_1}\right).$$

It follows, if we conceive H to act to the left at a distance, $r \frac{\sin \phi_1}{\phi_1}$, from the center, Fig. 4, that the moment, M, at a point $(r\ \phi)$, is given by H times

§ Professor Church, in "Mechanics of Internal Work", p. 118, derives the same formula, using H and the moment at an abutment as the unknowns. The writer used H and the moment at the crown as the unknowns, giving a shorter solution.

the perpendicular distance from $(r\ \phi)$ to this line of direction of H, the moments being positive (clockwise), for points between this line and the crown, and negative for the remaining points. This line of direction of H passes through the center of gravity of the arc, $A\ C$.

A remarkable analogy may now be pointed out in the case of water load or normal forces only. Thus, from Equation (10),

$$(p\ r - P_0) = \frac{2 \sin \phi_1}{D_0}\left(p\ r \frac{k^2}{r^2}\right),$$

and it is seen that the values of $\frac{2 \sin \phi_1}{D_0}$ are precisely those given in Table 2; so that the values of $(p\ r - P_0)$ and, thus of P_0, can be at once written down for the values of $2\ \phi_1$ and $\frac{t}{r}$ given.

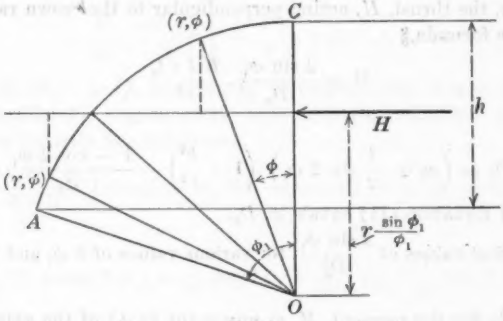

FIG. 4.

Further, if $(p\ r - P_0)$ is taken as a force, with the line of action of H in Fig. 4 only acting to the right, then, since by Equation (13),

$$M = -(p\ r - P_0)\ r \left(\cos \phi - \frac{\sin \phi_1}{\phi_1}\right),$$

the moment at any point $(r\ \phi)$, is equal to $(p\ r - P_0)$ multiplied by the perpendicular distance from $(r\ \phi)$ to the supposed line of action of $(p\ r - P_0)$. This striking property of the circular arch subjected to normal loads, has already been brought out in connection with Fig. 2.

If we let $h = r\ (1 - \cos \phi_1)$ equal the rise of the center line of the arch, then the formula for the crown deflection due to a temperature rise of t_0 degrees Fahr. is,

$$\eta_1 = \frac{h\ e\ t_0 \sin \phi_1}{D_0} \left[(1 + \cos \phi_1) \left(1 + \frac{k^2}{r^2} \right) - 2 \frac{\sin \phi_1}{\phi_1} \right]$$

Arch Hinged at Ends.—For a rise of temperature of t_0 degrees Fahr., the thrust, H, acting inward at an abutment along the span line is,*

$$H = \frac{E\ I}{r^2\ B}\ 2\ e\ t_0 \sin \phi_1$$

where,

$$B = \phi_1\ (2 + \cos 2\ \phi_1) - \frac{3}{2} \sin 2\ \phi_1 + \frac{k^2}{r^2} \left(\phi_1 + \frac{1}{2} \sin 2\ \phi_1 \right)$$

The moment at any point (r, ϕ) of the axis of the arch is,

$$M = H\ r\ (\cos \phi - \cos \phi_1).$$

The radial deflection at the crown is,

$$\eta = \frac{h\ e\ t_0}{B} \left[(1 + \cos \phi_1) \left(2\ \phi_1 \cos \phi_1 + \frac{k^2}{r^2} \sin \phi_1 \right) - \sin \phi_1\ (1 + 3 \cos \phi_1) \right]$$

The derivation of the formulas for deflection is so similar to that for normal forces that it is omitted.

When the Crown Deflection Is Given by Observation.—From formulas given, by expressing H (or the values of $(p\ r - P_0)$ in the case of normal forces) in terms of η $\left(\text{by first writing the ratios, } \frac{H}{\eta}, \text{ or, } \frac{p\ r - P_0}{\eta} \right)$ and substituting in the formula for M, formulas are derived of the form,

$$M = -\ a \left(\frac{E\ t^3}{r\ h} \right) \eta$$

In this formula, η is always positive for water pressure. For a fall of temperature, η is positive. For a rise in temperature, η is negative.

At the crown, $\phi = 0$, $M = M_0$, the values of the coefficients a, when the term in k is ignored, referring to the four cases indicated, are given in Table 3. The results are applicable to the crests of many curved dams,

TABLE 3.

$2\phi_1$	Fixed Ends.		Hinged Ends.	
	Water pressure.	Temperature.	Water pressure.	Temperature.
60°	0.159	0.170	0.096	0.105
90°	0.150	0.180	0.090	0.111
120°	0.138	0.188	0.083	0.121

where t is small and k can be ignored in the formulas. When η is given by observation, M_0 can be computed, if the influence of water pressure and temperature change can be separately estimated.

As dams are usually constructed, the ends are neither fixed nor hinged, so that the engineer is forced to use his judgment in selecting a coefficient,

* Professor Church gives one derivation of this formula in his "Mechanics of Internal Work", p. 109.

which should incline toward that for fixed or hinged ends according to the thickness of the arch and the conditions at the abutments.

Generally, the deflection, η, has been measured for a combined water pressure and change of temperature. If the deflections for each cannot be separately estimated, still some idea of the value of M_0 can be had, for a given $2\phi_1$, by taking for a a rough average of the four coefficients, having regard to the conditions at the ends.

To the stresses at the crown corresponding to the value of M_0 must be added the stresses due to P_0 or H. To estimate P_0 (the thrust at the crown due to water pressure), it is necessary to know p, the unit normal pressure carried by the horizontal arch at the crest. No rule can be given for any dam; but, for the Wooling Dam, p is roughly equal to the full water pressure at one-sixth or one-third of the depth of the dam below the crest, according as the dam is fixed or not fixed at the base.* If a complete solution has been made, as in the case of the Wooling Dam, then p *is* known and P_0 can be computed.

* See Tables 5 and 11 of the writer's discussion of Mr. Noetzli's paper on "Gravity and Arch Action in Curved Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), pp. 74 and 88. Also, some information can be drawn from Tables 8 and 12, as to estimating H, the thrust due to change of temperature.

DISCUSSION

L. J. MENSCH,* M. AM. SOC. C. E. (by letter).—This paper is a valuable addition to the literature on arches, and will dispel speedily and effectively many wrong ideas of designers of past and prospective arch dams.

In his discussion† of the paper by H. Hawgood, M. Am. Soc. C. E., entitled, "Huacal Dam, Sonora, Mexico", the writer has treated the thick arch in a similar manner. He designated the expression, $pr - P_0$, which is really a negative thrust or pull due to the shortening of the arch or a fall of temperature, by T, and believes he has made the action of the shortening of the arch appear more clearly than by compounding the whole action by the method of Castigliano. Since that time, the writer has found that it is not permissible to neglect the effect of shear for the lower arches of a dam and has been agreeably surprised that the formulas for thrust and deflection have not become more complicated and, in some cases, are even simpler than those where shear is neglected. For example, the author's Equation (11) becomes, when the effect of shear is included:

$$D = \left(\frac{1}{4}\sin 2\,\phi_1 + \frac{\phi_1}{2}\right) 2\,\phi_1 + \frac{k^2}{r^2}\left(2\,\phi_1 - \frac{1}{2}\sin 2\,\phi_1\right) 2\,\phi_1 - 2\sin^2\phi_1$$

Any process used to obtain formulas for thrust, moment, and deflections, is always complicated on account of the great length of the equations, the many fractions, plus and minus signs, indices, decimals, and the most skillful mathematician is led into many errors. The writer never considers a new problem solved, until the same result has been obtained by different processes at an interval of a year or more, or when the result is obtained by three persons working independently.

The work of preparing a paper like that of the author is very great, and only those who have tried similar original investigations have any idea of the energy expended on it. It is not surprising, therefore, that such a paper should contain errors. The writer questions Equation (18) and some of the deflection formulas, and many of the figures in Table 1. There seems to be an error in calculating P_0 for the arches 40 ft. thick, in the examples chosen by the author, because the values of $pr - P_0$ ought to be approximately one hundred times greater than for the arches, 4 ft. thick.‡ Arch action, as commonly understood, is small in flat thick arches, and a glance at a flat arch, as shown in Fig. 5, taken from an existing arch dam, will show that the effect of the horizontal components of the water pressure must be very small, and the simplest assumption is that the pressure is taken up by beam action. Can the beam carry this load? This question has not been considered by most writers on the subject. In this case, the water pressure amounts to 10 000 lb. per sq. ft. The corresponding bending moment equals $10\,000 \times \frac{100^2}{24} = 4.17 \times 10^6$ ft-lb. The moment of resistance is $\frac{40^2}{6}$ and the extreme fiber stresses, in pounds per square foot, are $\mp$ 15 000 at the crown and $\mp$ 30 000 at the abutments. It can-

* Gen. Contr., Chicago, Ill.

† *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 610.

‡ This error in the paper has since been corrected.

not be assumed that compression from the arch will reduce these tensile stresses very much, because the arch cannot deflect sufficiently to compress the fibers before they are cracked, or before cracks appear at the construction joints. The beam will show cracks, somewhat similar to those illustrated in Fig. 5. A

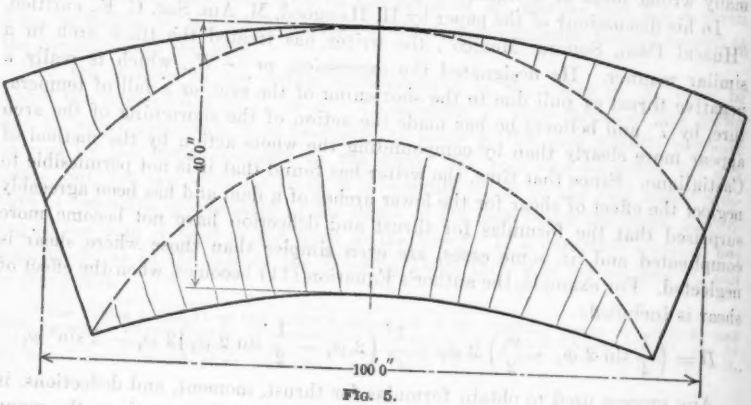

FIG. 5.

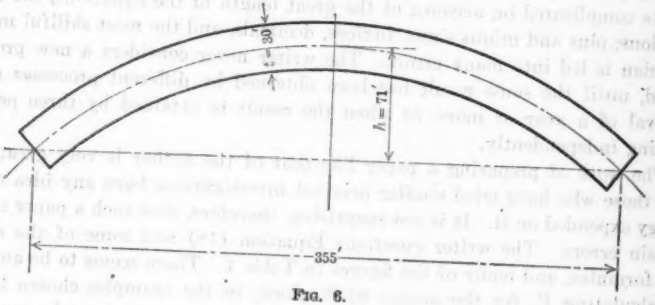

FIG. 6.

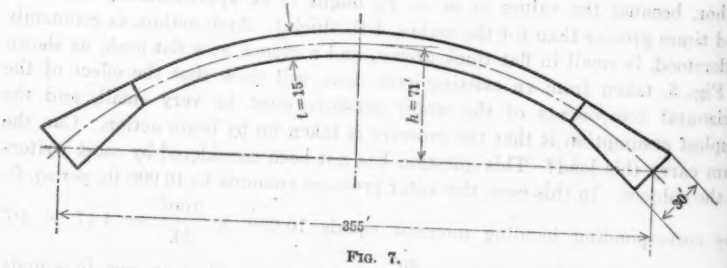

FIG. 7.

sound part of the beam will remain in the shape of a new arch which can act as a real arch, and the size of this new arch may be determined by the theory of least work. It might be objected that such cracks if they really existed would have been reported on dams already built. Calculations, however, show

that the sum of the width of all the cracks may be only $\frac{1}{7\,000}$ in., hence they would be considered to be hair-cracks only, if found at all. This action of the thick flat arch has been only vaguely understood and denominated as "wedge" action, although a wedge is not a recognized structural member.

It is clear that the new arch will show much higher stresses than those calculated on the whole section by the ordinary cylinder theory. The author, as well as F. A. Noetzli, Assoc. M. Am. Soc. C. E., believes that the stresses can be found from deflection measurements of the arch. The writer thinks that this method would lead to erroneous views. The modulus of elasticity is a greatly varying quantity. Even in a common cylinder test, the moduli on different sides of the cylinder often vary more than 100% and the figures given by authors are only averages. The best information on this subject is found in the report of the Committee of the Austrian Engineering Society on tests on a number of masonry and reinforced concrete arches (made in 1892 at an expense of $20 000) and the scientific treatise by Mr. J. A. Spitzer on the reinforced concrete arches of these tests.* Arches were loaded with known weights, acting at known points, and the deflections and changes of angles were observed carefully at many points. From the deflection, the modulus of elasticity was calculated to be 2 000 000 lb. per sq. in., up to a load about 30% less than that producing the first visible crack. At the first crack, the modulus was about one-half the value mentioned, and for higher loads was still much less.

There is another uncertainty about the modulus of elasticity, due to the flow or plasticity of concrete, and many phenomena cannot be explained unless a low modulus is assumed. Such is the case with the effect of a change in temperature or the shrinkage of the concrete, which are slow actions, in which the time factor plays an important rôle. Recent tests on the shrinkage of concrete and on the effect of temperature lead to the conclusion that the modulus of elasticity lies between 500 000 to 1 000 000 lb. per sq. in. for these actions and, in some cases, drops to 100 000 lb. per sq. in. and less. The stresses cannot be found from the deflections in an arch with contraction joints or cracks (unless the arch is properly reinforced), because the distribution of stresses in those planes is widely different from that obtained by the straight-line theory, once tensile stresses are calculated in the extreme fibers.

In this connection the writer wishes again to call the attention of the Profession to the unscientific character of the plain masonry or concrete arch dam, as commonly built. Fig. 6 shows a horizontal section of an arch dam which has been constructed. A non-reinforced arch like this might have been designed by the old Roman engineers. A modern bridge designer would never use it, because the stresses from temperature and shrinkage action will be larger than those from the live loads, and such an arch will crack. The latest information available indicates that the greatest shortening due to the combination of a fall in temperature and shrinkage of concrete for an arch of that thickness is about $\frac{1}{1\,800}$ of the length. The pull or negative thrust

* *Zeitschrift*, Osterreichischer Ingenieur und Architecten Verein, No. 20 (1896).

caused by this shortening, when the modulus of elasticity is 1 000 000 lb. per sq. in., can be obtained for an arch of that particular relation of rise to span, by the formula:

$$H = \frac{66\,000\,t}{\left(\frac{h}{t}\right)^2 + 1.26} \text{ lb. per lin. ft.}$$

when h equals the rise of the arch and t the thickness, in feet. This formula has been obtained in a similar manner, as shown in the writer's discussion of the Huacal Dam, previously referred to, except that the effect of shear was considered. By substituting $t = 30$ ft., $h = 71$ ft., $H = 9\,550 \times t = 286\,500$ lb. per lin. ft., and using Mr. Noetzli's approximation of $\frac{2}{3} \times h$ as the leverage of this pull on a section at the abutment, the moment there becomes:

$$286\,500 \times 47.33 = 13.55 \times 10^6 \text{ ft-lb.}$$

The moment of resistance of the section being $\frac{30^2}{6}$, the extreme fiber stresses at the abutment are $\pm$ 90 500 lb. per sq. ft. The component of the pull, tangent to the arch at the abutment, is about 220 000 lb. and the corresponding tension, $\frac{220\,000}{30} = 7\,333$ lb., or the extreme fiber stresses, — 97 833 lb. and + 83 167 lb., respectively. The arch will crack or expansion joints will open, which fact is amply confirmed by actual observation of that dam. The water pressure does not entirely relieve the arch of the tensile stresses. It produces only a compression of 47 000 lb. per sq. ft.; therefore, the arch must act as a reduced section, as previously described for the very thick arch, with much higher stresses than the 47 000 lb. assumed by the designer.

Assume, now, that the arch has a section similar to that shown in Fig. 7. On account of the enlargement at the abutment, the negative thrust will be comparatively larger than that for an arch of a uniform thickness, and approximately is given by:

$$H = \frac{100\,000\,t}{\left(\frac{h}{t}\right)^2 + 2}$$

or,

$$H = 61\,500 \text{ lb.}$$

The leverage of this force about a section at the abutment also becomes greater and will be assumed to be 50 ft.; therefore, the moment at the abutment is $61\,500 \times 50 = 3\,075\,000$ lb., and the extreme fiber stresses are $\frac{3\,075\,000}{\frac{30^2}{6}} = 20\,500$ lb. per sq. ft. The direct tensile stresses are, approximately, 1 440 lb., and the total stresses are — 21 940 and + 18 060 lb., respectively. The compressive stresses from the water pressure being 47 000 lb. at the abutment, will more than counterbalance the tensile stresses, but will not prevent the opening of contraction joints when the dam is empty. This can be prevented only by properly reinforcing the arch and

anchoring the reinforcing bars into the rock walls at the abutments. The writer hopes to have shown that with a saving of nearly 50% in masonry, lower stresses are produced in a reinforced concrete dam than in the plain concrete arch of to-day, and this without the fear of dangerous cracks.

That reinforced concrete arches are much more economical than plain concrete arches was unquestionably brought out by the Austrian tests, previously mentioned. A concrete arch of 76 ft. span, 15 ft. rise, 6.5 ft. wide, and 27.5 in. thick throughout, was tested to failure by the application of a total load of 185 000 lb., uniformly distributed on one side of the arch.

A reinforced concrete arch of the same span, rise, width, with a crown thickness of only 13¾ in., increasing to 25 in. at the abutment, failed at a much higher load, namely, 322 000 lb., distributed on the half span.

The arch dam of the future should not show larger cracks than modern arch bridges, and with richer concrete and proper reinforcement, there is no reason why stresses as high as those calculated for other reinforced concrete work should not be used. Thoughtful engineers may object to the use of reinforcement on account of the danger of the steel rusting by the action of intrusive water; there is no more danger that this will happen in dams than in reinforced concrete water tanks and reinforced concrete sewers, the general use of which is older than modern reinforced concrete buildings and bridges. Of course, richer concrete must be used, and the face of the dam should be water-proofed by any of the excellent methods which have proved successful in tunnels and high tanks. It is a fact, that most reinforced concrete tanks, in which the concrete acts in tension only, are comparatively much thinner than most concrete arch dams. Should similar structures in which the concrete acts primarily in compression be made thicker for the only reason that there may be some similarity with a gravity dam?

According to the writer's opinion, every arch ring of a dam should be designed to carry the entire water pressure, including all secondary stresses, proper allowance should be made for the effect of shrinkage and temperature in thick sections being very much less than in thin sections, as the concrete in the interior has no chance to dry out or to become affected to any extent by a change in temperature, and cracks should be prevented by proper reinforcement.

In large arch dams, as a rule, it is uneconomical to assume the arch rings to be affected only by the water pressure. If the weight of the arch ring is also considered, it will be found that the most economical design is obtained by inclined arches, the inclination being given by the ratio of water pressure per square foot to total weight of the inclined ring per linear foot. The reinforced concrete arch dam should be considered as a monolith, affected by the entire water pressure, the weight of the structure, and the inclined reactions of the side-walls. The inclined rings will take up most directly the inclined reactions and will relieve the base of the dam from the superimposed load; therefore, the supposed favorable influence of Poisson's ratio cannot be considered when the reservoir is full and the high stresses from the cantilever action do not exist at the base in a reinforced concrete dam. The rings have different inclinations at different depths and become nearly horizontal at the base of the dam.

During a stay on the Pacific Coast, the writer made a design on these lines for a reinforced concrete arch dam 210 ft. high, and 400 ft. long at the river bed, and found that a section 35 ft. thick at the base had much smaller stresses than would be found in a plain concrete curved dam of twice the thickness.

Engineers may be afraid to use comparatively thin, reinforced concrete arches on account of the supposed column action in such slender arch rings. The writer knows of only one test of a concrete arch where failure was produced by an uniform load over the entire span. This test was made by the Blaubeuren cement mill, in Ehingen on the Danube, on a three-hinged arch of 66 ft. span, 5 ft. rise, 4¾ in. thick at the crown, 8¾ in. thick at the abutment, and 12½ in. thick at the ¼-in. point. The structure was loaded for 7 years from 1896 to 1903, and failed after the last increase of load had been on it for 4 years. The maximum compressive stresses were calculated to be 840 000 lb. per sq. ft., although 12-in. cubes, cut from the structure afterward, failed at 954 000 lb. A reduction of compressive stress is found in tests of short columns, and the test of this slender arch does not indicate that column action is to be feared in arched dams.

The writer hopes that Professor Cain's paper will be considered carefully by all engineers interested in dam construction and will induce them to use more science and less speculation in the design of single and multiple-arch dams.

B. F. Jakobsen,* Assoc. M. Am. Soc. C. E. (by letter).—The author has presented an interesting and valuable paper on an important subject. He seems to possess in an unusual degree the happy faculty of the born mathematician of presenting a complicated and highly mathematical subject in such a manner as to make it readable and, therefore, doubly valuable. Even a cursory reading of the paper affords an understanding of the assumptions made therein, the analytical methods used, and the methods given for using the formulas.

Equations (12) and (13) are general formulas and, therefore, should apply for any value of the radius, r. As a matter of fact, when r approaches infinity, and the central angle approaches zero, the two formulas do give the correct bending moments for a straight beam fixed at both ends and loaded uniformly with p lb. per sq. ft. From Equations (12) and (10), we have, writing x in place of ϕ_1:

$$M_0 = \frac{x - \sin(x)}{x} \cdot \frac{p\, k^2\, 2\, x \sin(x)}{\left(1 + \frac{k^2}{r^2}\right)[x^2 + 0.5\, x \sin(2x)] - 2 \sin^2(x)}$$

If the width of the canyon is L ft., then:

$$r = \frac{L}{2 \sin(x)} \qquad (20)$$

since x is half the central angle. Also,

$$\sin(x) = x - \frac{x^3}{6} + \frac{x^5}{120} - \frac{x^7}{5\,040} + \cdots$$

and for small values of the angle, x,

$$\sin(x) = x - \frac{x^3}{6} \qquad (21)$$

* Designing Engr., San Joaquin Light and Power Corporation, Fresno, Calif.

For an angle of 60°, the error in Equation (21) is less than 1 per cent. Introducing Equations (20) and (21) in the equation for M_0 and dividing by x^4:

$$M_0 = \frac{2\,p\,k^2}{6} \cdot \frac{1 - \frac{x^2}{6}}{-\frac{x^2}{18} + 4\,\frac{k^2}{L^2}\left(2 - \frac{4}{3}\,x^2 + \frac{5}{18}\,x^4 - \frac{x^6}{54}\right)} \quad \ldots\ldots(22)$$

and for $x = 0$,

$$M_0 = \frac{p\,L^2}{24}$$

and this is the equation for the bending moment in the center of a straight beam fixed at the ends and loaded uniformly with p lb. per sq. ft.

Likewise, Equation (13) for the moment at the abutments becomes, after introducing Equations (20) and (21) and dividing by x^4:

$$M = \frac{2\,p\,k^2}{6} \cdot \frac{2 - \frac{7}{12}\,x^2 + \frac{x^4}{24}}{-\frac{x^2}{18} + 4\,\frac{k^2}{L^2}\left(2 - \frac{4}{3}\,x^2 + \frac{5}{18}\,x^4 - \frac{x^6}{54}\right)} \quad \ldots\ldots(23)$$

and for $x = 0$,

$$M = \frac{p\,L^2}{12},$$

which is the formula for the bending moment at the end of a straight beam loaded uniformly with p lb. per sq. ft.

Equations (22) and (23) may be used for computing the moments for any angle likely to occur in dam design. As already pointed out, Equation (21) is correct within 1% for central angles of 120 degrees. For small values of the central angle, Equations (22) and (23) give nearly exact values.

From Equations (22) and (23), the relative values of the bending moments can be more readily seen than from the original equations. It is evident that the bending moment at the abutment is always considerably larger than that at the crown, but as x increases this difference decreases. The statement* by F. A. Noetzli, Assoc. M. Am. Soc. C. E., in his paper on "The Relation Between Deflections and Stresses in Arch Dams", that "in a fixed arch, the bending moments at the arch abutments resulting from the thrust, H, are approximately twice as large as at the crown," is seen to be incorrect; for example, for a central angle of about 120°, that is, x is nearly one, the bending moment at the abutment is less than 1.5 times the moment at the crown, and for larger values of the central angle this is further reduced. It may also be noted, that Equation (14) for the shear may be obtained from Equation (13) by differentiation, as is the case for a straight beam.

Equation (15) which gives the deflection at the crown for an arch fixed at the abutments, was also checked by substituting Equations (20) and (21), dividing by x^6, and setting $x = 0$, when Equation (15) becomes:

$$\text{Deflection} = \frac{p\,L^4}{16\,E\,t^3}$$

which is the deflection in the center of a straight beam fixed at the ends and loaded uniformly with p lb. per sq. ft.

* See p. 289.

No doubt the same result can be found from the formulas given for the hinged arch; the writer does not believe that the assumption of a hinged arch is ever satisfied in dams, although the assumption of fixed ends certainly is, whenever no excessive tension is found at the abutments by the formulas for fixed arches.

The author assumes a constant modulus of elasticity and neglects the deformation due to shear and the influence of the water soaking of the upstream face. In a thin arch, this should not lead to any appreciable error and, in the writer's opinion, the long, slender arches near the top of a dam are those most difficult to design properly, since little assistance is afforded from cantilever action. When no tensile stresses are found at the abutments, and when the central angle is large, say, 120° or thereabouts, the spreading of the foundation must be negligible, especially as the total force on the abutment is small for a thin arch, and it seems to the writer that, in this case, the assumption of fixed ends agrees very closely with the actual conditions. With the nearly exact formulas of the author, it is possible to determine the stresses in the top of the dam instead of relying on the Rankine formula and using low stresses in the computations in order to take care of the uneven distribution of stresses through the section.

To facilitate calculations, the writer has plotted the author's Table 2 on Fig. 8. This was done by plotting on semi-logarithmic paper the values of $\frac{2 \sin \phi_1}{D_0}$ for the various angles, one curve for each value of $\frac{t}{r}$, and then interpolating. To illustrate the formulas with a thin arch, suppose $\frac{t}{r} = 0.02$ and $2\phi_1 = 40°$, and let $p = 864$ lb. per sq. ft., $r = 50$ ft. and, therefore, $t = 1$ ft. The Rankine formula gives:

$$r' \times p' = s \times t = r \times p$$

$$s = \frac{864 \times 50}{1} = 43\,000 \text{ lb. per sq. ft.} = 300 \text{ lb. per sq. in.}$$

The author's formulas give:

$$p\,r = 864 \times 50 = 43\,200 \text{ lb. per sq. ft.}$$

$$p\,r - P_0 = 2\,750 \times \frac{864}{12 \times 50} = 3\,980 \text{ lb. per sq. ft.}$$

At the crown:

Extrados = 440 lb. per sq. in. (compression)
Intrados = 108 lb. per sq. in. (compression)

At the abutment:

Extrados = 57 lb. per sq. in. (tension)
Intrados = 607 lb. per sq. in. (compression)

For an arch with the same thickness and radius and the same loading, except that $2\phi_1 = 180°$,

$$p\,r - P_0 = 6.7 \times \frac{864}{600} = 14.4 \text{ lb. per sq. ft.}$$

Therefore, practically, $pr = P_0$, the bending moments are practically zero, and the Rankine formula applies very nearly.

$\frac{t}{r} =$

FIG. 8.

As an example from an actual dam, we may consider the Kerckhoff Dam.* This is a constant-angle arch dam, approximately 110 ft. high, with Taintor gates, 14 ft. high, on top. At Elevation 970, with water standing 10 ft. above the top of the Taintor gates:

$$h = 25 \text{ ft.};$$
$$t = 9.88 \text{ ft.};$$
$$r' = 205 \text{ ft.};$$
$$r = 200 \text{ ft.};$$
$$\frac{t}{r} = 0.0494$$
$$2\phi_1 = 122°$$

The author's formulas for an arch fixed at the abutments give:

$$p \times r = 321\,000 \text{ lb.}$$
$$p \times r - P_0 = 2\,220 \text{ lb.}$$

Therefore, at the crown:

Extrados = 257 lb. per sq. in. (compression)
Intrados = 191 lb. per sq. in. (compression)

and, at the abutments:

Extrados = 156.5 lb. per sq. in. (compression)
Intrados = 300 lb. per sq. in. (compression)

The Rankine formula gives 225 lb. per sq. in. The maximum shear exists at the abutment; by the author's Equation (14), and assuming a parabolic distribution through the cross-section, it is only 2 lb. per sq. in., and the deformation due to shear, it would seem, would certainly be negligible.

At Elevation 900:

$$h = 95 \text{ ft.};$$
$$t = 289 \text{ ft.};$$
$$r' = 157.7 \text{ ft.};$$
$$r = 143.3 \text{ ft.};$$
$$\frac{t}{r} = 0.201;$$
$$2\phi_1 = 82° \ 40'.$$

This gives:

$$p \times r = 935\,000 \text{ lb.}$$
$$p \times r - P_0 = 350\,000 \text{ lb.}$$

Therefore, at the crown:

Extrados = 357 lb. per sq. in. (compression)
Intrados = 75 lb. per sq. in. (tension)

At the abutments:

Extrados = 246 lb. per sq. in. (tension)
Intrados = 568 lb. per sq. in. (compression)

* See the writer's article, "Design and Construction Features of the Kerckhoff Dam", *Engineering and Contracting*, June 8th, 1921, p. 565.

The Rankine formula gives 225 lb. per sq. in. Computing the shear at the abutment as before, we find the maximum shear equals 83.3 lb. per sq. in. Although the maximum compression has about doubled, the shear, in this case, is forty times as great as previously stated.

It is worth noting in this connection that the water load gives moments of opposite signs to the moments due to a rise in temperature (see Figs. 2 and 4).

A temperature increase of 5° Fahr., for the Kerckhoff Dam, at Elevation 900, and with $E = 144 \times 3\,000\,000$; $e = 0.0000055$, gives:

$$H_0 = 128\,000 \text{ lb.} = 30.7 \text{ lb. per sq. in.}$$

and, since for any angle, ϕ,

$$H = H_0 \cos \phi$$

there is obtained for the temperature stresses alone:

At the crown:

Extrados = 47.3 lb. per sq. in. (tension)
Intrados = 108.7 lb. per sq. in. (compression)

At the abutments:

Extrados = 172 lb. per sq. in. (compression)
Intrados = 126 lb. per sq. in. (tension)

Combining the water loading due to 95 ft. of head with the loading due to a temperature rise of 5° Fahr.:

At the crown:

Extrados = 310 lb. per sq. in. (compression)
Intrados = 34 lb. per sq. in. (compression)

At the abutments:

Extrados = 74 lb. per sq. in. (tension)
Intrados = 442 lb. per sq. in. (compression)

It is quite evident, therefore, that grouting the dam under pressure or closing it at or near the end of the coldest season, as suggested by L. R. Jorgensen,* M. Am. Soc. C. E., must be beneficial. A comparatively large increase in the compressive stresses is not a matter of great importance, and the method evidently makes it possible to reduce the undesirable tensile stresses.

That the influence of shear will be much greater with thick arches than with thin arches with the same central angle may be seen by comparing the shear in the two examples given by the author on page 239.

In the first example:

$$p\,r - P_0 = 0.00265\,p\,r$$

Since $t = 4$ ft.,

$$P = 0.25\,p\,r$$

in which P is in pounds per square foot, and if parabolic distribution of the shear is assumed, then,

$$S = \frac{1.5 \times 0.00265\,p\,r \times 0.866}{4} = 0.00086\,p\,r$$

* "Improving Arch Action in Arch Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 316.

in which S is in pounds per square foot, and, therefore,

$$\frac{P}{S} = 290$$

Therefore, the shear is certainly negligible compared with the normal stresses.

From the second example, we have:

$$p\,r - P_0 = 0.219\,p\,r$$

and, since $t = 40$ ft.,

$$P = 0.0223\,p\,r$$

in which P is in pounds per square foot, and the shear is,

$$S = 0.0071\,p\,r$$

in which S is in pounds per square foot, and, therefore,

$$\frac{P}{S} = 3.14.$$

In the first example, the maximum shear is about one-third of 1% of the normal stress, while in the latter case, the shear is about one-third of the normal stress, or relatively speaking, nearly one hundred times greater than in the first example.

If r is assumed to be the same in both cases, but p in the second case is ten times as great as in the first case, because t is ten times greater, then the maximum shear in the two cases is:

$$\frac{0.00086}{0.071} = \frac{1}{82}$$

In the second case, the shear stresses are eighty-two times greater than in the first case.

It would seem, therefore, that for thick arches, when the central angle is not too small, the author's Equation (5) should include the elastic work for shear. This is:*

$$L = \frac{1}{2\,G}\int d\,x \int\int S^2\,dy\,dz$$

or, for a rectangular section of unit width, since,

$$G = \frac{E}{2.4}, \text{ and } d\,x = r\,d\,\phi$$

$$L = 2.88\,\frac{r}{2}\int_0^{\phi_1} \frac{S^2\,d\,\phi}{E\,t}$$

Also, in the thick arch, there is more likelihood of a considerable difference in temperature between the up-stream and down-stream faces, and the assumption of a constant modulus of elasticity is much more questionable, because the difference between the stresses in the up-stream and down-stream faces is considerable and much greater than is the case with thin arches. Finally, in actual dams, the thick arches are near the base and considerably affected by cantilever action and the weight of the concrete above.

In the example of the Kerckhoff Dam, the tension in the up-stream face at the abutment, at Elevation 900, would be 246 lb. per sq. in., if it is assumed that

* "Elasticität und Festigkeit", C. Bach, Third Edition, p. 349.

the arch sustains the entire water pressure. The arch would fail, therefore, if it was loaded as assumed; but if account is taken of the shear deformation and of the variability of the modulus of elasticity,* a different result would be obtained, and this arch would probably require a load several times greater than the assumed load before it would fail.

The author's Equation (15) gives the deformation at the crown for an arch fixed at the abutment. From this formula, we should be able to estimate the deflection of a free arch. For thin arches, the formula should give correct values, that is, values which agree with the modulus of elasticity of the material in the arch. For thick arches, the writer believes the correspondence would be much smaller for the reasons previously given. As an illustration of very large deformations in a concrete dam which has not produced cracks, the Salmon Creek Dam† might be mentioned. At Elevation 1075, there is a very decided knee in the deflection curve, and this would require a vertical tensile stress of 2 750 lb. per sq. in., if the deformation is to be accounted for by deflection due to bending under the influence of a uniformly distributed load. In spite of this, no cracks have been reported in the down-stream face, and it is not likely, therefore, that any exists. The assumption generally made, that the deflection is due to bending alone, is not correct.‡ The deflection due to shear is likely to be several times greater than the deflection due to bending, so that the tensile stress, when correctly computed, would be, perhaps, one-third of the value previously given. If this stress really existed, it would not fail to produce cracks, and, therefore, it may serve as an excellent illustration of the great circumspection necessary when concluding, from the measured deflections, the magnitude and nature of the stresses in a large concrete arch.

It should also be borne in mind that the deflection which occurs the first time the dam is loaded is not an elastic deformation, or as expressed by Messrs. Eddy and Turner§:

"Initial loading, however, is certain to develop noticeable deviations from perfect elasticity because of shrinkage stresses developed in the hardening of the cast concrete. A few repetitions of loading largely eliminates such deviations, so that the theory of work and the elastic theory of deformation becomes applicable and proves a practical and precise method of treatment."

To this should be added the influence of the internal heating due to the setting or curing of the cement and also the influence of lateral stresses which in a large concrete dam cannot be altogether negligible.

The author has solved an important problem in dam design in an exact and sufficient manner, and his solution will be of great help to engineers who have to design large arch dams.

FRED A. NOETZLI,‖ ASSOC. M. AM. SOC. C. E. (by letter).—Professor Cain's paper is a valuable contribution to the theory of arch dams, and it is to be hoped

* See the writer's discussion on "Gravity and Arch Action in Curved Dams", by F. A. Noetzli, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 95.

§ "Concrete-Steel Construction", Part I, p. 76.

‖ Chf. Engr., Beckman and Linden Eng. Corporation, San Francisco, Calif.

that tests will soon be made in order to determine to what extent the behavior of such dams agrees with exact theory.

The study of the problem of arch dams, and with due consideration of the historical development of arch dam designs, has brought the writer to the conclusion that in the present state of knowledge with regard to modulus of elasticity, range of temperature, etc., of the dam material, it would be just as well to use, as a beginning, approximations for the sake of simplicity. More or less successful attempts toward a correct solution have been made. Most of these calculations, however, had their merits buried, for the average reader, in higher mathematics, etc., and the new formulas, due to their complicated nature, were ignored by the busy designer.

The assumptions on which, at the present time, any theory of arch dams has to be based, still involve a considerable degree of uncertainty. This is, in the case of large arch dams, particularly true with regard to the modulus of elasticity, range of temperature, degree of shrinkage of concrete, "fixity" of the arches, swelling, lateral expansion (Poisson's ratio), secondary arch action, "wedge" action, etc., so that a high degree of accuracy in the formulas used is not of much value. Before extensive tests have been made, the modulus of elasticity can hardly be judged and its uniformity guaranteed within 20% of any assumption, and this is also true of the range of temperature, as well as the degree of shrinkage. Assuming for the other uncertainties involved another 20%, for all four assumptions together there is a probable error of,

$$\sqrt{20^2 + 20^2 + 20^2 + 20^2} = 40\%$$

which is probably conservative for thick dams. Consequently, if approximate formulas are within 20 to 25% of the theoretically correct values they may be considered, for the present, as sufficiently accurate as compared to the probable error of 40% in the assumptions.

Theoretically exact formulas, however, are desirable as long as they can be expressed in a simple form. Fortunately, the author's final equations go far toward this end, which makes his paper doubly valuable.

Professor Cain has also included in his investigation the thick and the flat arches, as they may occur in the lower parts of arch dams. Mr. Mensch has expressed doubts as to the correctness of some of the deflection formulas and certain coefficients of Table 1. There is no question that by also considering the effect of shear, slightly larger deflections will be found for short and thick arches than are obtained from the author's Equation (15).

However, it is rather questionable whether such thick and flat structures should be classified as arches. For instance, the author has calculated that for an arch with a radius of 135 ft., with a thickness of 40 ft., and a central angle of 40°, only 2½% of the load is supported by what is usually called arch action. The remainder of the load, or 97½%, is assumed, by the author, to be carried by beam action.

Mr. Mensch has shown why beam action cannot be relied on to carry the load. The writer wishes to point out why "secondary" arch action within the masonry may prevail in such a case. From Fig. 5, it is seen that there is the possibility that within the large arch, a secondary arch is formed,

approximately as shown by the dotted lines.* For the size of arch chosen by the author, a smaller arch with a radius of approximately 52 ft. and a thickness of 20 ft., may be inscribed. According to the cylinder formula, the stress in the large arch would be:

$$f_c = \frac{p\,r}{t} = p\,\frac{135}{40} = 3.37\,p$$

The stress in the small arch for the same load would be obtained at,

$$f'_c = \frac{p\,r}{\frac{t}{2}} = p\,\frac{52}{20} = 2.60\,p,$$

or even less than in the large arch. Thus, the small arch, due to the shorter radius, seems to be stronger than the large one. This reasoning indicates that secondary arch action will prevail in such a case. The size, shape, and stresses of the secondary arch can be determined by Castigliano's theory of least work. For the present purpose, it will be sufficient to indicate that arch formulas applied to such "arches" as shown in Fig. 5 may lead to erroneous conclusions. Giving due consideration to such limitations of the author's theory, it is seen that the discrepancies between his exact arch deflection formula and the writer's approximation† is comparatively small for all true arches as may occur in arch dams.

It is of further interest to note that the author's method of calculating the arch deflection stresses, due to rib-shortening and temperature changes, furnishes results that check almost exactly those obtained by the writer's method, using the coefficients from the curves of Figs. 4 and 5 of his paper, "The Relation Between Deflections and Stresses in Arch Dams".‡ Consequently, the arch deflection stresses, calculated from measured deflections, will also be about the same if the same assumptions as to temperature, etc., are made.

It may not be amiss to warn against an indiscriminate application of the author's as well as the writer's "deflection stress" formulas. Those equations give reliable results for unreinforced arches only if, during the state of the deformation considered, the arches have no open tension cracks. If the calculations show tension in a dam to such a degree that the construction joints may open (for instance, at a tension of 50 lb. per sq. in.), these formulas can no more be applied directly. They then will indicate only that the compression stresses are distributed unevenly over the arch.

Mr. Jakobsen questions the correctness of a statement made by the writer on page 289 of his paper previously mentioned, that "in a fixed arch, the bending moments at the arch abutments resulting from the thrust, H, are approximately twice as large as at the crown." This is no doubt due to a misunderstanding on the part of Mr. Jakobsen, inasmuch as the thrust, H, goes through the center of gravity of the arch, and this one is located, for arches to a central angle of 120°, at very nearly one-third of the rise from the crown and two-thirds of the rise from the abutments of the arch. Consequently, the lever arm for H, at the abutments, is twice as large as at

* On this point, see, also, the writer's investigations on "vertical arching" in dams, *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 36.

† "Gravity and Arch Action in Curved Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 11.

‡ See pp. 304 and 305.

the crown and, therefore, the bending moments also, due to H. Mr. Jakobsen apparently mistakes the moment given by the Equations (21) and (22), which include thrust and bending, with the moment from H (Fig. 4), which is due to temperature or rib-shortening.

WILLIAM CAIN,* M. AM. SOC. C. E. (by letter).—To assist the practical engineer in the solution of "the circular arch under normal loads", Tables 1 and 2 have been much extended, and are given as Tables 4, 5, and 6. The coefficients in the starred rows were computed, the others being interpolated. In effecting the interpolation, curves were drawn for $\frac{t}{r}$ constant, and $2\phi_1$ variable, so that separate curves were drawn for $\frac{t}{r} = 0.00, 0.02, \ldots, 0.30$, in turn, from which the ordinates could be obtained for given values of $2\phi_1$. Where the curvature was appreciable, the results, for the interpolated values, are approximate, since they depend on how the curves are drawn between the points, as given by computation; but it is believed that the interpolated coefficients are sufficiently near the truth for use in practice. In fact, most of the interpolated values are practically exact. The regularity of the curves drawn to a large scale is the most convincing proof of the accuracy of the computations, although the formulas were changed to other but equivalent forms, for a few independent computations, as an additional check.

TABLE 4.—CIRCULAR ARCH FIXED AT ENDS, UNDER NORMAL LOADS.

*180°	1.637	1.637	1.636	1.636	1.634	1.632	1.630	1.627

NOTE.—All values were computed.

Table 6 gives the values of $\frac{2 \sin \phi_1}{D_0}$, to be used in the computation of either $(p\,r - P_0)$ or H (for temperature changes), for an arch "fixed at the ends", or one without hinges.

On account of the great variation in the coefficients, Mr. Jakobsen's plan of using semi-logarithmic paper for the complete graph, was adopted. It is shown in Fig. 10.*

In his paper entitled, "The Relation Between Deflections and Stresses in Arch Dams", page 305, Mr. Noetzli has derived the formula:

$$H_t = k_t \frac{t^3}{h^2} E\,e\,t_0$$

for the thrust on the crown section, due to a temperature change of t_0 degrees, in which the influences of moment and tangential thrusts are considered. The coefficients, k_t, are to be taken from Fig. 5 of his paper.

The writer's formula for H, the thrust due to a temperature change, for an arch without hinges, can be expressed in the form last given, where k_t is replaced by,

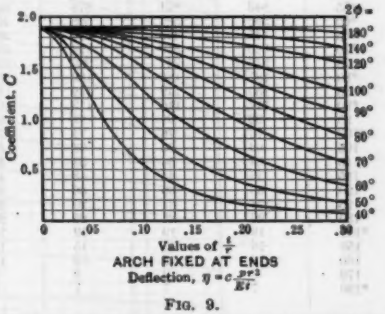

FIG. 9.

* To include properly the interpolated values, Figs. 9 and 10 should be drawn to larger scales. A very satisfactory size for the engraved part of the semi-logarithmic paper is 12 in. square, with two logarithmic scales in the vertical direction. If the upper limit is marked 1 000, all values of Table 6 over 1 000, will not be represented; but such values are rarely needed, since they correspond to the smaller values of $\frac{t}{r}$ coupled with the smaller central angles.

$$\frac{(1 - \cos \phi_1)^2}{12} \cdot \frac{2 \sin \phi_1}{D_0},$$

so that numerical values are readily computed by utilizing the values given in Table 6. This was done for a wide range of values of $\frac{t}{h}$ and $2\phi_1$. The numerical results were compared with the corresponding ones taken from Mr. Noetzli's Fig. 5 and were found to agree very well, thus affording a valuable check on the accuracy of the computations. Mr. Noetzli's Fig. 5 would have to be extended to cover the same range as the writer's Table 6 or Fig. 10; but, even then, it is compact and avoids the use of semi-logarithmic paper, so that there seems to be a practical advantage in expressing results in terms of $\frac{t}{h}$. A corresponding table should preferably give k_t to three significant figures.

TABLE 6.

$$(p\,r - P_0) = \frac{2 \sin \phi_1}{D_0} \left(p\,r \frac{k^2}{r^2} \right)$$

and tangential stress, the influence of shear being disregarded. It was originally assumed that the action of the right half of the arch on the crown section of the left half, was equivalent to a tangential thrust, P_o, and a couple, the moment of which was M_o. The value of this moment, as given by Equation (12), is,

$$M_0 = -(p\,r - P_0)\,E\,C,$$

where,

$$E\,C = r\left(1 - \frac{\sin\phi_1}{\phi_1}\right).$$

This moment is, therefore, always negative. The corresponding couple is left-handed, so that the original forces at the crown, Fig. 11 (*a*), can be replaced by the forces shown in Fig. 11 (*b*). On cancelling the two forces, $P_0 - P_0$, at C, there is left the single tangential force ($p\,r$), acting to the left at C, and the single force ($p\,r - P_0$), acting to the right at *E*, (Fig. 11 (*c*)); and these two forces are exactly equivalent to the original couple (the moment of which is M_0) and the tangential thrust, P_0, both acting at the crown.

It can be shown similarly, for an arch hinged at the ends, that the couple, the moment of which is M_o and the thrust, P_o, both acting at the crown section, can be replaced by a single force ($p\,r - P_o$), acting to the right along the span line, *A B*, Fig. 11, and a single force ($p\,r$), acting to the left, at the center of the crown, in a tangential direction.

Messrs. Jakobsen and Mensch have called attention to the desirability of ascertaining the influence of shear, especially for thick arches and small central angles. Consequently, it has been thoroughly investigated, and some numerical results will shortly be given to show the decrease in moment due to shear for various values of $2\,\phi_1$ and ratio of $\frac{t}{r}$.

The formula for the elastic work due to shear by Bach (as quoted by Mr. Jakobsen), for the half arch, is,

$$2.88\,\frac{r}{2}\int_0^{\phi_1}\frac{S^2\,d\,\phi}{E\,t}$$

For an isotropic body (or one having equal elasticity in all directions), the coefficient 3.00 is used in place of 2.88.

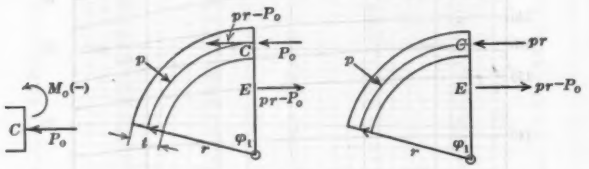

FIG. 11.

On adding the expression just given to the right member of Equation (5), the symbol, *L*, will then represent the internal elastic work due to moment, thrust, and shear.

The shear, S, as given by Equation (14), is,

$$S = (p\,r - P_0)_s \sin \phi.$$

Therefore,

$$\frac{\delta S}{\delta M_0} = 0; \quad \frac{\delta S}{\delta P_0} = -\sin \phi.$$

Since the shear at the crown is zero, there are only two unknowns, M_0, P_0, to determine. By the method of least work, these can be found by elimination between the two equations:

$$\frac{\delta L}{\delta M_0} = 0, \quad \frac{\delta L}{\delta P_0} = 0.$$

The solution proceeds exactly as before and is very simple. It leads to the formula,

$$(p\,r - P_0)_s = \frac{p\,r}{D_s}\, 2\, \frac{k^2}{r^2}\, \phi_1 \sin \phi_1,$$

where,

$$D_s = D + 2.88\, \frac{k^2}{r^2}\, \phi_1 \left(\phi_1 - \frac{1}{2} \sin 2\, \phi_1\right),$$

D being given by Equation (11).

The subscript, s, indicates that shear is included. The term involving 2.88 as a factor, expresses the influence of shear. When 2.88 is replaced by 3.0, as for an isotropic body, the value of D_s reduces to that given by Mr. Mensch.

When the term involving the factor, 2.88, is omitted, the value of $(p\,r - P_0)$, as given by Equation (10), where shear was neglected, is derived.

Let the moment at the crown when shear is omitted be designated by M_o, and when shear is included, by M_s. Then, since Equations (7) and (12) hold, for the case when shear is included on replacing $(p\,r - P_0)$ by $(p\,r - P_0)_s$,

$$M_s = -(p\,r - P_0)_s \left(1 - \frac{\sin \phi_1}{\phi_1}\right),$$

$$M_0 = -(p\,r - P_0) \left(1 - \frac{\sin \phi_1}{\phi_1}\right),$$

therefore,

$$\frac{M_s}{M_0} = \frac{(p\,r - P_0)_s}{(p\,r - P_0)} = \frac{D}{D_s}.$$

The values of D and D_s were computed for various values of $2\,\phi_1$, t, and r, and their ratio, which is that of M_s to M_o, was inserted in Table 7.

The decrease in the moment at the crown due to shear seems to be negligible for central angles from 90 to 120°, and it only amounts to 10.2% for

$$2\,\phi_1 = 40° \text{ and } \frac{t}{r} = \frac{40}{135} = 0.297.$$

The derivation of the formula for deflection at the crown, when shear is included, involves long and tedious reductions, so that only a few steps will be given. For an arch without hinges, shear being included, by Equation (14),

$$S = (p\,r - P_0)_s \sin \phi$$

When the small radial force, w, is applied at the crown, the shear is,

$$S' = S + w \cos \phi \therefore \frac{\delta S'}{\delta w} = \cos \phi.$$

On adding the work due to shear and proceeding as on page 240, we derive,

$$\frac{E I}{r}\eta = \int_0^{\phi_1} M r \sin \phi \, d\phi + k^2 \int_0^{\phi_1} P \sin \phi \, d\phi + 2.88 \, k^2 \int_0^{\phi_1} S \cos \phi \, d\phi.$$

TABLE 7.—ARCH FIXED AT ENDS. RATIO, $\frac{M_s}{M_0}$.

$2\phi_1$	r, in feet.	t, in feet.	$\frac{M_s}{M_0}$	Percentage of decrease due to shear.
40°	135	4	0.979	2.1
40°	135	20	0.909	9.1
40°	135	40	0.898	10.2
90°	300	30	0.952	4.8
120°	900	30	0.971	2.9
120°	135	4	0.997	0.3

After substituting the values of M, P, and S, integrating and reducing, the value of $(p r - P_0)_s$ is eventually introduced, and the equation solved for the deflection, η, giving:

$$\eta = \frac{p r^2}{E t} \frac{(1 - \cos \phi_1)\left\{\left(1 + \frac{k^2}{r^2}\right)(\phi_1 - \sin \phi_1) + 2.88 \frac{k^2}{r^2}(\phi_1 + \sin \phi_1)\right\}}{\left(1 + \frac{k^2}{r^2}\right)\left(\phi_1 + \frac{1}{2}\sin 2\phi_1\right) - \frac{1 - \cos 2\phi_1}{\phi_1} + 2.88 \frac{k^2}{r^2}\left(\phi_1 - \frac{1}{2}\sin 2\phi_1\right)}$$

The influence of shear is represented by the terms containing the factor, 2.88, which, in this case, are found in both numerator and denominator.

As a numerical illustration of the influence of shear, take an arch for which, $2\phi_1 = 60°$, $t = 20$ ft., $r = 200$ ft.; whence, $\frac{t}{r} = 0.1$, $\frac{k^2}{r^2} = \frac{1}{12}\left(\frac{t}{r}\right)^2 = 0.0008333$. When shear is included, the formula gives:

$$\eta = 1.2963 \frac{p r^2}{E t}.$$

On omitting the terms containing 2.88 as a factor, the deflection, when shear is neglected, is found to be,

$$\eta = 1.2772 \frac{p r^2}{E t},$$

or the influence of shear adds 1.5% to the deflection, in this case. From Table 1, for $2\phi_1 = 60°$, $\frac{t}{r} = 0.1$, there is found, $c = 1.277$, which agrees with the coefficient just found, as computed from an equivalent formula.

As to the accuracy of the formulas, since most of the steps have been given, it is easy for any one to verify them. The writer has carefully checked them, and some errors in copying have been noted.* On pages 239 and 243, the second examples given, for $t = 40$ ft., $r = 135$ ft., should have the central

* These errors have since been corrected in the paper.

angle, $2\,\phi_1 = 40°$ and not $2\,\phi_1 = 120$ degrees. Among others, Mr. Mensch has properly called the writer's attention to these two errors.

As Mr. Mensch questions Equation (18), it seems proper to give some of the steps in the reduction, so that any one can easily verify the result. From Equations (16) and (4),

$$\frac{\delta\, M}{\delta\, P_0} = r\,(\cos\phi - \cos\phi_1);\quad \frac{\delta\, P}{\delta\, P_0} = \cos\phi.$$

On substituting these values in Equation (17), and also the values of M and P given by Equations (16) and (4), we derive,

$$r^2\,(P_0 - p\,r)\int_0^{\phi_1}(\cos\phi - \cos\phi_1)^2\,d\,\phi$$
$$+\,k^2\int_0^{\phi_1}\Big\{(P_0 - p\,r)\cos^2\phi + p\,r\cos\phi\Big\}\,d\,\phi = 0$$

On integrating and solving for $(p\,r - P_0)$, Equation (18) is readily derived. The denominator was first derived in another form and then reduced to the form given in Equation (18). It is instructive to compute the stresses of the flat arch, Fig. 5, and compare results with those given by Mr. Mensch for a straight beam fixed at the ends. The span, l, is 100 ft., the thickness, t, 40 ft., and the radius of the center line of the arch, as measured, on the drawing, is $r = 140$ ft.; consequently, $2\,\phi_1 = 41°\,50'$, $\frac{t}{r} = 0.286$, and $k^2 = \frac{1}{12}(40^2)$. Also, from Table 6, $\frac{2\sin\phi_1}{D_0} = 144$.

Mr. Mensch gives the pressure per square foot on the extrados as 10 000 lb.; therefore, the unit pressure on the center line is,

$$p = 10\,000 \times \frac{160}{140} = 11\,430 \text{ lb. per sq. ft.}$$

Equation (10), or its equivalent, gives,

$$(p\,r - P_0) = \frac{2\sin\phi_1}{D_0}\,p\,\frac{k^2}{r} = 1\,567\,000;$$

whence, $P_0 = 33\,000$ lb. From Equation (12), $M_0 = -\,4\,840\,000$ ft-lb. The unit stresses at extrados and intrados are found from the formula,

$$s = \frac{P}{t} \pm \frac{6\,M}{t^2},$$

to be, at the crown,

18 970 lb. per sq. ft. compression at extrados.
18 220 lb. per sq. ft. tension at intrados.

At the abutment, the moment, M_1, is found from Equation (13), for $\phi = \phi_1$, to be $M_1 = 9\,613\,000$ ft-lb.; and the tangential thrust, P_1, as computed from Equation (4), is $P_1 = 136\,000$ lb. The resulting unit stresses are;

39 400 lb. per sq. ft. compression at the intrados.
32 600 lb. per sq. ft. tension at the extrados.

For the straight beam, fixed at the ends, the extreme fiber stresses are, $\mp$ 15 000 lb. per sq. ft. at the crown, and $\mp$ 30 000 lb. per sq. ft. at the abutments.

The radial deflection at the crown of the arch is given by the formula:

$$\eta = c \frac{p r^2}{E t},$$

where c, by interpolation from Table 4, is found to be nearly, 0.115.

The deflection for the straight beam, subjected to the uniform loading, $p' = 10\,000$ lb. per sq. ft., can be found by the well known formula:

$$\frac{p' l^4}{32 E t^3} = \frac{p}{E t} \frac{1}{32} \left(\frac{5 r}{7}\right)^2 \left(\frac{l}{t}\right)^2 = 0.10 \frac{p' r^2}{E t};$$

whence,

$$\frac{\text{Deflection of arch}}{\text{Deflection of beam}} = \frac{0.115}{0.100} \frac{p}{p'} = 1.31$$

The computations have been given in full on the hypothesis that the concrete could stand the tension. Since this is not true, the arch would crack, about as illustrated in Fig. 5.* The comments by Mr. Mensch relative to Figs. 6 and 7 are instructive, and the writer is glad to note that he endorses the reinforcing of arch dams and the tying of them in to the rock walls at the abutments. The writer does not think that "stresses can be found from deflection measurements of the arch", where the dam has vertical cracks, unless the deflection and temperature of the dam, at the time of closing of the dam, are recorded. He has made a reservation to that effect in his discussion† of Mr. Noetzli's paper previously mentioned, and, in addition, has referred to the uncertainty relative to the modulus of elasticity.

The subject of inclined dams, commented on by Mr. Mensch, is important, as is known from a study of multiple-arch dams, and it will well repay careful investigation.

Mr. Jakobsen's discussion is not only interesting, but helpful. By taking the span constant and developing the formulas for moments, for an arch fixed at the ends, into series, and, ultimately, taking the limit, as the central angle approaches zero and the radius increases indefinitely, the arch approaches, as a limit, the straight beam with fixed ends, and the formulas for moments at crown and abutments are found to reduce to the corresponding moments for the straight beam at the center and ends. It is a "deadly" test that an exact formula can stand and one that approximate formulas generally fail to meet. It is a test easily made and will doubtless send to the scrap heap a number of formulas confidently proposed. All the formulas for moments and deflections of the writer's paper meet this test; and, to that extent, they may be said to be checked.

* If the uncracked portion of the arch, Fig. 5, is supposed to constitute another arch, the dimensions (as roughly measured from the drawing) will be as follows: Radius, r, of center line = 50 ft., span of center line = 84 ft., thickness of arch, t = 18 ft. The central angle is, consequently, $2\phi_1 = 114° 18'$. On solving as before, it is found that there is no tension anywhere in this new arch, and that the greatest compression is 956 lb. per sq. in. at the intrados at the abutment. The large central angle accounts mainly for the great difference in the results.

† See p. 308.

In the solution, just given, pertaining to the flat arch, Fig. 5, it was found that the stresses at the crown and abutments, as well as the crown deflection, approach the corresponding quantities for the straight beam. Further, the center of pressure at the crown section is $\frac{M_0}{P_0} = -146.7$ ft., from its center, on the extrados side. As the central angle tends toward zero, this center of pressure should recede indefinitely from the crown. To test this, the formula for P_0 was expanded in series, after r was expressed in terms of the span, l, and it was found to approach zero as ϕ_1 decreased indefinitely. Hence, since $M_0 = -\frac{1}{24} p l^2$, when $\phi_1 = 0$, therefore, $\frac{M_0}{P_0} = -\infty$. The same conclusion was reached for the arch hinged at the ends, where the bending moment at the crown, expressed in series, is,

$$M_0 = -p k^2 \frac{1 - \frac{1}{4}\phi_1^2 \cdots}{\frac{4}{15}\phi_1^2 \cdots + \frac{8k^2}{l^2}\left(1 - \frac{2}{3}\phi_1^2 \cdots\right)}$$

This reduces to $\left(-\frac{p l^2}{8}\right)$ for $\phi_1 = 0$, the moment at the center of a straight beam, supported at the ends, when uniformly loaded. It was proved, first, that $P_0 = 0$, when $\phi_1 = 0$, and, again, that $\frac{M_0}{P_0} = -\infty$ for $\phi_1 = 0$. The formulas for deflection afford equally satisfactory checks. Thus, substituting, $r = \frac{l}{2 \sin \phi_1}$ in Equation (15), for an arch fixed at the ends, and expanding,

$$\eta = \frac{p}{E t} \frac{\frac{l^2}{48}\left(1 + \frac{1}{3}\phi_1^2 \cdots\right) + k^2 \phi_1^2 \left(\frac{1}{12} + \cdots\right)}{\frac{2}{45}\phi_1^2 \cdots + \frac{8k^2}{l^2}\left(1 - \frac{2}{3}\phi_1^2 \cdots\right)},$$

which, for $\phi_1 = 0$, reduces to, $\frac{1}{32}\frac{p l^4}{E t^3}$, as for a straight beam, when shear is omitted. When shear is included, to compare with the usual formulas, replace the factor, 2.88, by 3.00, in the formula for deflection given previously. To find the deflection due to shear only, use only the terms in the numerator having the factor, 2.88, now replaced by 3.00. After expansion, we derive,

$$\eta = \frac{\frac{3}{2}\frac{p k^2}{E t}\left(2 - \frac{1}{3}\phi_1^2 \cdots\right)}{\frac{2}{45}\phi_1^2 \cdots + \frac{8k^2}{l^2}\left(1 + \frac{1}{3}\phi_1^2 \cdots\right)},$$

which reduces, for $\phi_1 = 0$, to $\frac{3}{8}\frac{p l^2}{E t}$, the exact expression given in textbooks for a straight beam uniformly loaded.

The total deflection, when shear is included, for a straight beam, uniformly loaded and fixed at the ends, is thus,

$$\eta = \frac{p l^4}{32 E t^3} + \frac{3}{8}\frac{p l^2}{E t} = \frac{p l^4}{32 E t^3}\left[1 + 12\left(\frac{t}{l}\right)^2\right].$$

Apparently, the influence of shear, as $\frac{t}{l}$ increases, is more pronounced for the beam than for the arch.

The deflection of an arch hinged at the ends, is given by Equation (19). When this is expressed in terms of l and expanded, there is found,

$$\eta = \frac{p}{E\,t}\,\frac{\frac{1}{2}\left(1-\frac{1}{12}\,\phi_1^2\ldots\right)\left\{\frac{l^2}{4}\,\frac{\frac{5}{6}}{1-\frac{1}{3}\,\phi_1^2}+\frac{1}{6}\,k^2\,\phi_1^2\left(1-\frac{\phi_1^2}{20}\ldots\right)\right\}}{\frac{4}{15}\,\phi_1^2+\frac{2}{3}\,\frac{t^2}{l^2}\left(1-\frac{2}{3}\,\phi_1^2\ldots\right)}$$

which, when $\phi_1 = 0$, reduces to,

$$\frac{5}{32}\,\frac{p\,l^4}{E\,t^3},$$

the known formula for a straight beam.

The value of $(p\,r - P_0)$ given by Equation (10) for fixed ends, and by Equation (18) for hinged ends, does not lead to known formulas as $\phi_1 \doteq 0$; but on dividing by $(p\,r)$, putting in the right member, $r = \frac{l}{(2\,\sin\,\phi_1)}$, and developing; then, as $\phi_1 \doteq 0$, $r \doteq \infty$, and for a straight beam, $P_0 = 0$, either equation gives, at the limit, $1 = 1$.

Finally, Equations (10), (15), (18), and (19) were deduced independently for $\phi_1 = 90$ degrees. The results checked with those given by these formulas for this angle.

The writer's paper was prepared for the practical engineer and every care was used to insure accuracy in both the formulas and the tables. They are believed to be accurate for the following reasons:

(1).—The formulas for temperature thrust, H_0, for either fixed or hinged ends, agree exactly with those deduced by Church by a different procedure.

(2).—The quantity, D_0, appears in the denominators of the formulas for H, $(p\,r - P_0)$, M, and the deflection, η, for the arch with fixed ends. The expression designated by B appears, similarly, in the denominators of the formulas for H, $(p\,r - P_0)$, M, and η, for the arch with hinged ends.

(3).—As the central angle diminishes, the formulas for moments and deflections for an arch with a fixed span—whether with fixed or hinged ends—approach indefinitely the corresponding formulas for a straight beam, and the center of pressure at the crown recedes indefinitely.

(4).—As the central angle diminishes, the two members of the formulas for $(p\,r - P_0)$ approach an identity as a limit and P_0 tends to zero.

(5).—The formulas for $(p\,r - P_0)$ and for deflection, for both fixed and hinged ends, for the special case, $\phi_1 = 90°$, were derived independently. The results agreed with those given by the general formulas for $\phi_1 = 90$ degrees.

(6).—As to the tabular quantities, the regularity of the corresponding curves is the most convincing proof of their accuracy, though a few check

computations were made by use of the formula, written in a different but equivalent form.

(7).—The coefficients of Table 2, when expressed in terms of $\frac{t}{h}$, are found to agree fairly well with those of Mr. Noetzli's Fig. 5, previously mentioned, thus affording a mutual check of results. Also, the coefficient of Mr. Noetzli's formula for deflection gives a rough check to many of the figures of Table 1. The computations of the quantities in Tables 1 and 2, and 4, 5, and 6, was a formidable task, but a systematic procedure lightened the labor and insured greater accuracy.

Mr. Mensch states that he "questions Equation (18) and some of the deflection formulas and many of the figures in Table 1". It is to be hoped that the reasons given in favor of their accuracy, may incline Mr. Mensch to check the various steps in the analysis; when, perhaps, all doubts as to their accuracy may be removed. When possible, it is desirable for the sake of scientific verity, that objections should be specific, so that the author may know what point to meet. In this way, the truth is more quickly attained.

Mr. Jakobsen seems to be under the impression that the expanded formulas may be best for computing moments. The writer has not found that to be the case for any of the formulas. After deriving the formulas for thrusts, moments, and deflections, they were at once expanded, in hope, that, by using the expanded form, numerical computation would be easier; but it was found that too many terms of the series would have to be taken to give sufficient accuracy and the method was abandoned.

It may seem superfluous to some that the writer has introduced into the discussion of curved dams the arch hinged at the ends. B. A. Smith,* M. Am. Soc. C. E., says:

"Unless extraordinary precautions are taken to fix in direction the ends of the arch, *A* and *B*, there will be deflections at these points which will correspond very nearly to the deflections due to no bending moment at *A* and *B*".

If there is sound rock on the hillsides at the ends of the successive horizontal arches, and these ends are fixed to the hillsides with the same care as is used with a reinforced concrete bridge, then any arch may be regarded as "fixed at the ends". It would be instructive if constructors would state the actual conditions. It is very doubtful if "extraordinary precautions" to fix the ends of the arches are generally taken, and a yielding abutment will invalidate any theory.

Some years ago, Professor Malverd A. Howe, M. Am. Soc. C. E., constructed an experimental reinforced concrete arch† to test the reliability of his summation formulas. The measurements were of such a refined character that *H*, *V*, and *M*, at an abutment, could be accurately ascertained; but, at first, the measurements did not correspond with the computations for an arch fixed at the ends. Although the fixed abutment was of the usual design, it was eventually found to move; but the movement was so small that it was

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 2030.

† See description of arch, apparatus, and measurements, with discussion of results, in *Railway Age Gazette*, March 26th, 1909.

difficult to determine that it did move. However, when the abutment was thoroughly tied to the masonry walls of the house by rods, the larger errors were corrected, theory and observation were reconciled, and the results were regarded as very satisfactory.

For arched dams, the theory for hinged ends may only apply to very thin arches; but, if the thicker arches are only loosely connected with the hillsides, the moments, thrusts, and deflection may be intermediate in value to those for fixed and hinged ends.

It is well to state again what was emphasized on the first page of the writer's paper, that it is the part of the normal load on any horizontal arch, as determined by a correct analysis, that figures in all the computations. Thus, for water pressure, p' (except at one point) is not the unit pressure due to the depth of water at the arch on the extrados, but it is supposed to be the value given by Mr. Smith's analysis, or by Mr. Noetzli's tentative method, when applicable. We have then, p = normal unit pressure on the center line of the arch $= \frac{p' r'}{r}$. The value of p at the crest, where the water pressure is nil, is often very large.*

Thus, for the Wooling Dam fixed at the base, with reservoir full, the greatest unit stress in a horizontal arch is at the crest, where $p' = 363$ lb. per sq. ft.; whereas, for the same dam, not fixed, but simply supported, at the base, the greatest unit stress is in an arch about 10 ft. below the crest, where $p' = 755$ lb. per sq. ft. The full water pressure at the base of the dam is 2 062 lb. per sq. ft., and it is seen that nothing like this pressure is exerted on any arch of the dam. Another caution refers to temperature stresses. The horizontal thrust, H, as deduced in this paper for a temperature change, pertains only to an arch perfectly free to move except for the restraints at the abutments. For the actual horizontal arch of a curved dam, the movement of the arch under a temperature change is resisted by the dam acting as a cantilever. Both influences must be considered for an arch regarded as a part of the dam. This is done in the notable paper of Mr. B. A. Smith on "Arched Dams"†, and also in the discussion by the writer of Mr. Noetzli's paper on "Gravity and Arch Action in Curved Dams".‡ The analysis is approximate and not as exact as that pertaining to water pressure.

On the basis of this analysis,§ if p' = normal unit pressure on the extrados of the horizontal arch considered, from the water load and temperature change combined, and using Smith's formula for deflection, the total deflection, D, in feet, due to both causes, is,

$$D = \frac{3}{2} \frac{p' r'^2}{E t} - e r' t_0,$$

* See the writer's discussions in *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), pp. 74, 88; also p. 310.

§ *Loc. cit.*, pp. 81 to 87.

in which,

e = coefficient of expansion for 1° Fahr. —0.0000055; and

t_0 = change of temperature, in degrees, positive for a rise, negative for a fall of temperature.

By using the writer's more general expression for deflection, where the coefficients, c, may be taken from Table 4 or Table 5, according as the arch is regarded as fixed or hinged at the ends, we have,

$$D = c\,\frac{p\,r^2}{E\,t} - e\,r\,t_0,$$

where $p = \dfrac{p'\,r'}{r}$, is the normal pressure, in pounds per square foot, on the center line of the arch, r being the radius of that center line, as before.

On solving for $(p\,r)$,

$$(p\,r) = \frac{E\,t}{c\,r}(D + r\,e\,t_0),$$

t_0 being positive for a rise, and negative for a fall, in temperature. For an arch that is not cracked, if D is an observed deflection, the formula will give the value of $(p\,r)$, provided the arch is in compression. It will tend to give confidence in the results if, for observed deflections, computed deflections are substituted, as for the thoroughly worked out case of the Wooling Dam, simply supported at the base.*

The computed values are as follows, for the crest: Water pressure: deflection = 0.362 in.; T = 94 600 lb. per sq. ft.; temperature fall of 20° Fahr.; deflection = 0.270 in.; T = 23 170 lb. per sq. ft. Both deflections are down stream and compression is exerted in both cases.

The combined deflection is thus $D = \dfrac{0.632}{12}$ ft., and the combined tangential thrust = 117 770 lb.

The computations were based on Smith's formula and value of $c = 1.50$; hence, to compare results properly, write r' for r, or, what amounts to the same thing, in the last formula, let r = 135 ft.; then, for t = 2.2 ft., $t_0 = -20°$, $E = 144 \times 2\,000\,000$ lb. per sq. ft., we derive,

$$(p\,r) = 118\,300 \text{ lb.},$$

which compares very well with T = 117 770 lb., the thrust for the combined water pressure and temperature change.

In the discussion by the writer, previously cited, the formula for deflection, including the cases where T is either tension or compression, is treated fully to prove that the last formula is general if attention is paid to the signs: D is positive when down stream and t_0 is as indicated. The applications to the Barren Jack Dam and the Salmon Creek Dam will show the method to follow when deflection observations are given, provided there are no cracks and the arch is in compression.

* The revised computation for this dam, using 8-place logarithmic tables, is given in the writer's discussion of Mr. Noetzli's paper on "The Relation Between Deflections and Stresses in Arch Dams", p. 310.

In case of vertical cracks, observations should be made of temperature and deflection at the time of the complete closing of the cracks. Then, similar observations are to be made at a subsequent period, and the difference in the temperatures will represent t_0 and the difference in the deflections will give the value of D to insert in the formulas. The uncertainty with regard to what value to assign to E, and the fact that the temperature of a dam is not uniform, particularly for thick dams, will render only an approximate solution in the general case. However, if the deflection observations are taken at the same time as the temperature, a large part of the uncertainty is eliminated, particularly if the air temperature, at the time of the two observations, has not varied for several days at the periods considered. From the value of (pr), as computed for any dam, since r is known, the value of p can be formed. If this happens to be greater than, or even nearly as large as, the unit water pressure at the base of the dam, the results should be rejected, for it would indicate, either that there were vertical cracks in the dam, that there was a lack of sufficient precision in the observations, or that the temperature was far from being uniform throughout the dam.

To complete the analysis, reference will now be made to Table 3, with the accompanying formula for the moment, M_0, at the crown of the horizontal arch considered:

$$M_0 = -a\left(\frac{E\,t^3}{r\,h}\right)\eta,$$

where the deflection, η, is positive for either water pressure or a fall of temperature, and negative for a rise of temperature.

Continuing the solution for the Wooling Dam, supposed not to be fixed at the base,

Let,

$$\eta_w = \text{deflection for water load} = \frac{0.362}{12}\text{ ft.},$$

$$\eta_t = \text{deflection for } 20° \text{ fall of temperature} = \frac{0.270}{12}\text{ ft.},$$

therefore,

$$\eta_w + \eta_t = D = \frac{0.632}{12}\text{ ft.},$$

and,

$$\eta_w = 0.573\ D,\ \eta_t = 0.427\ D.$$

Suppose the very thin arch to be regarded as hinged at the ends; then, from Table 3, for $2\ \phi_1 = 120°$, $a = 0.083$ for water pressure, and $a = 0.121$ for temperature change, $t_0 = -20°$, therefore,

$$M_0 = -\frac{E\,t^3}{r\,h}[0.083\ \eta_w + 0.121\ \eta_t] = -\frac{E\,t^3}{r\,h} \times 0.1\ D.$$

On substituting, $E = 288\,000\,000$, $t = 2.2$, $r = 135$, $h = 67.5$, $D = 0.0527$, we derive,

$$M_0 = -1\,774 \text{ ft-lb.}$$

For a dam, for which η_w and η_t have not been computed, and only D is given by observation, the values of η_w and η_t, in terms of D, will have to be

estimated. Some information for such an estimate can be had from the computed values of the Wooling Dam. From Equation (16), for the Wooling Dam, hinged at the ends, since $M = M_0$ when $y = h$,

$$(p\,r - P_0) = \frac{-M_0}{h} = \frac{1774}{67.5} = 30 \text{ lb.}$$

therefore,

$$P_0 = p\,r - 30 = 118\,300 \text{ lb. (say).}$$

The unit stresses at the crown are:

390 lb. per sq. in., compression at the extrados.
358 lb. per sq. in., compression at the intrados.

To effect the solution for the arch fixed at the ends, the proper values of a must be taken from Table 3 and the value of M_0 computed as before. Then, from Equation (12), $(p\,r - P_0)$ can be found and the value of P_0 computed. If desired, the value of M at the abutment can be found from Equation (13) by placing $\phi = \phi_1$.

The deflection lines for the Barren Jack Dam are given in Fig. 1* of Mr. Noetzli's paper on "The Relation Between Deflections and Stresses in Arch Dams," the greatest deflection of 0.58 in. occurring on May 25th, 1909, at the crest, with reservoir full, the air temperature being 47° Fahr. On December 24th, 1908, with an empty reservoir, the temperature was 87° Fahr., and the deflection zero at the crest. We have, therefore, $D = \frac{0.58}{12} = 0.0483$ ft., $t_0 = -40°$; and, using the dimensions given by Mr. Noetzli, $r = 79$ ft., $h = 24$ ft., $t = 2$ ft., whence $2\,\phi_1 = 91°\ 45'$.

Assuming this thin dam to be hinged at the ends, from Table 5,

$$c = 1.58,\ r\,e\,t_0 = -79 \times 0.000\,0055 \times 40 = -0.01738,$$

$$E = 144 \times 2\,500\,000 \text{ lb. per sq. ft.}$$

Therefore,

$$(p\,r) = \frac{E\,t}{c\,r}(D + r\,e\,t_0) = 0.0309\,\frac{E\,t}{c\,r} = 125\,800 \text{ lb.}$$

From Table 3, the coefficients to be used are 0.083 and 0.121, respectively, so that if it is assumed, arbitrarily,

$$\eta_w = 0.4\,D,\ \eta_t = 0.6\,D \therefore (0.083\,\eta_w + 0.121\,\eta_t) = 0.106\,D.$$

Therefore,

$$M_0 = -\frac{E\,t^3}{r\,h}(0.106\,D) = -7\,780 \text{ ft-lb.}$$

$$p\,r - P_0 = \frac{-M_0}{h} = 324 \therefore P_0 = 125\,500 \text{ lb.}$$

The corresponding stresses at the crown of this arch are,

517 lb. per sq. in. compression at the extrados.
354 lb. per sq. in. compression at the intrados.

If the modulus, E, is reduced, the stresses will be reduced nearly as the ratio of the two moduli.

The deflection lines of May 25th, 1909, and of August 10th, 1909, for this dam, are crossed, which throws doubt on the accuracy of the observed deflec-

* See p. 295.

tions. Of course, if there were any cracks not entirely closed, at the time of the observation, when the reservoir was empty, which was probably the case, the results given are misleading and should be rejected.

With regard to the supposed flow or plasticity of concrete, and its varying modulus, it is to be hoped that a curved dam will be built so thoroughly reinforced and tied to the hillsides, that no cracks can form. Then, if precise observations of deflections and temperatures are taken, it should be possible, by the use of the given formulas, to obtain reliable results, provided the value of E is known. To determine that would require a complete solution of the dam, such as has been effected for the Wooling Dam, so that the value of p for any horizontal arch is known; then on solving the equation,

$$D = c\,\frac{p\,r^2}{E\,t} - e\,r\,t_0,$$

for E, its numerical value could be ascertained. It is preferable, of course, to eliminate temperature change by using observations for deflections, for different heights of water, when the dam is at the same temperature.

It has been stated that the solution of Mr. B. A. Smith,* pertains strictly to thin dams. This is evident from the derivation of Equation (1) of the paper cited,

$$\frac{d\,F}{d\,z} - \frac{T}{R} + p = 0$$

When the shear, F, between the successive horizontal arches, is ignored, this reduces to the ordinary cylinder formula, $T = p\,R$, which is only true for the linear arch, or practically true for a thin arch. In a number of examples of thick arches with small central angles, discussed by the writer, as the arch represented by Fig. 5, it has been seen that the cylinder formula is totally inapplicable.

As such thick arches, with small central angles, only occur near the base in a V-shaped valley, it is possible that Mr. Smith's method may lead to practical results. No other rational method has as yet been proposed for the dam not fixed at the base. For the dam fixed at the base, the tentative method will apply, since the coefficients, c, of Tables 4 and 5 take account of the deflections, as $\frac{t}{r}$ and the central angle vary. This is true if the shear between the horizontal arches can be practically ignored, which can be done, as proved by the writer, for thin dams, such as the Wooling Dam.

Formulas for the deflection of the circular arch, for fixed ends, and also for hinged ends, for a rise of t_0 degrees Fahr., have been given on page 247. Mr. A. E. Greene has suggested to the writer, that, in deriving the formulas, "no account was taken of that part of the deflection of the crown which takes place without any work being done on the structure when the temperature changes. * * * If the arch was on rollers, the crown deflection would be $h\,e\,t_0 = r\,e\,t_0\ (1 - \cos\,\phi_1)$ and this should be added to the deflections given." The point is well taken, and it is perhaps well to make the reasoning as clear as possible and then effect the corrections. For

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 2027.

the case of the arch with fixed ends, regard the arch temporarily as fixed at the right end, but free to move horizontally at the left end. Thus (1), under the rise of temperature, the arch being free to expand, the rise, h, will be increased by $h\,e\,t_0$, and the free end will move to the left a distance, $2\,r \sin\phi_1\, e\, t_0$. Then, for this expanded arch (2), a horizontal force, H, acting inward and a couple, M_t, are supposed to be applied at the free end, of such magnitudes that the section there is brought back to its original position. In this second stage, work is done, and the solution of the corresponding work equations give the values of H and M_t, or of H and M_0; and the corresponding formula for crown deflection corresponds only to this increase in h due to the forcing back of the free end of the expanded arch to its original position; therefore, the total deflection at the crown must equal this value derived by aid of a work equation added to the deflection for the free arch.

Since deflections away from the center have been assumed to be negative, the deflection, η_1, given on page 247, corresponding to the second stage previously mentioned, is really negative, so that $-\,h\,e\,t_0$ must be added to it to give the total deflection, which is, of course, negative for a rise of temperature.

After the (algebraic) addition and reduction, it is found that the total deflection for the arch with fixed ends, is,

$$\eta = -\,c\,(r\,e\,t_0),$$

where c is the coefficient of $\dfrac{pr^2}{E\,t}$ in Equation (15) and its numerical value for various values of $2\,\varphi_1$ and $\dfrac{t}{r}$ can be obtained from Table 4.*

It can next be shown that the value of a in the formula,

$$M_0 = -\,a\,\frac{E\,t^3}{r\,h}\,\eta,$$

*Another solution can be briefly indicated. For the free arch under the rise of temperature, the unit elongation along or parallel to the axis is $e\,t_0$. Suppose (1), this elongation is caused by a tangential tension, P', therefore,

$$P' = t \times E\,e\,t_0 = \frac{E\,I}{k^2}\,e\,t_0,$$

When (2), the expanded arch is brought back to its original position at the abutments by the forces, H and M_t, the total tangential component at $r\,\phi$ is,

$$P = H\cos\phi - P' = \frac{E\,I}{r^2}\,(e\,t_0)\,\frac{2\sin\phi}{D_0}\cos\phi - \frac{E\,I}{k^2}\,e\,t_0.$$

The value of M, page 245, is,

$$M = -\frac{E\,I}{r}\,e\,t_0\,\frac{2\sin\phi_1}{D_0}\left(\frac{\sin\phi_1}{\phi_1} - \cos\phi\right).$$

For an arch subjected to the normal unit loads, p, the value of P is found from Equations (4) and (10), and the value of M from Equations (10) and (13). These values become identical with those for temperature change if one places

$$p\,k^2 = -\frac{E\,I}{r}\,(e\,t_0);\ \text{or,}\ p\,r = -\frac{E\,I}{k^2}\,(e\,t_0) = -\,E\,t\,(e\,t_0).$$

Since the deflection under the loads, $p = c\,\dfrac{r}{E\,t}\,(p\,r)$, by the reasoning of page 240, the deflection under the temperature rise of t_0 degrees is,

$$\eta = c\,\frac{r}{E\,t}\,(p\,r) = -\,c\,(r\,e\,t_0).$$

Similar results follow for the arch with hinged ends.

for a change of temperature, is given for fixed ends by the formula,

$$a = \frac{1}{6} \frac{1 - \frac{\sin \phi_1}{\phi_1}}{\left(\frac{\phi_1}{\sin \phi_1} - 1\right)\left(1 + \frac{k^2}{r^2}\right)},$$

which is likewise the formula corresponding to water pressure.

Similar reasoning for the arch with hinged ends will show that, under a rise of t_0 degrees of temperature, the total crown deflection is,

$$\eta = - c \ (r e t_0),$$

where c is the coefficient of $\frac{p r^2}{E t}$ of Equation (19), the numerical values of c being given in Table 5 for various values of $2 \phi_1$ and $\frac{t}{r}$.

The coefficient, a, in the formula for M_0, for the arch with hinged ends, whether for water pressure or a change of temperature, is,

$$a = \frac{1}{6} \frac{\sin \phi_1 (1 - \cos \phi_1)}{\sin \phi_1 + \phi_1 (1 - 2 \cos \phi_1) + \frac{k^2}{r^2} (\phi_1 - \sin \phi_1)}.$$

In the formula for M_0, a is always positive, and the deflection, η, is positive for either water pressure or a fall of temperature (t_0 negative) and negative for a rise of temperature (t_0 positive).

It now remains to revise the table of coefficients, a (Table 3), in accordance with the foregoing determinations, the results, as given in Table 8, being true for thin arches.

TABLE 8.

$2\phi_1$	Fixed Ends.		Hinged Ends.	
	Water pressure.	Temperature.	Water pressure.	Temperature.
60°	0.159	0.159	0.096	0.096
90°	0.150	0.150	0.090	0.090
120°	0.138	0.138	0.083	0.083

It is fortunate that the coefficients for water pressure and temperature are the same, for, now, no uncertainty can exist for the case of combined water pressure and temperature change.

This change in the coefficients pertaining to temperature changes will affect some of the results given in connection with observed deflections of the Barren Jack Dam, but the changes are obvious and will affect the final stresses only slightly, therefore, the corrections are not given either for the examples of this paper or in the discussion by the writer of Mr. Noetzli's paper previously mentioned.

Mr. Noetzli properly calls attention to the uncertainties regarding the modulus of elasticity, temperature changes, and other assumptions on which

the theory of arched dams is based. There are other assumptions made in the analysis, which are only approximately true. Thus, in Mr. B. A. Smith's analysis, the radius of the extrados of a horizontal arch is substituted for that of the center line, so that the results are strictly true only for a very thin arch. Also, the writer has assumed p (the part of the unit normal load carried by the arch) as constant for any one horizontal arch, although it possibly varies from crown to abutment. Again, although the writer proved, for the thin Wooling Dam, that the successive horizontal arches could be regarded as free to slide over each other, yet this hypothesis may not be practically true for thick arches. Thus, the computations for arched dams generally lead to approximate results, the case being analogous to that of trusses where secondary stresses are either ignored or allowed for under a sufficient factor of safety. However, in view of all these uncertainties in the assumptions, it is well to use as accurate an analysis as possible, so as not to add other uncertainties by a solution that is only roughly approximate.

Mr. Noetzli refers to the possible marked influence of shear on the deflections for a thick arch. It has been fully discussed by the writer, in what precedes, for the arch with fixed ends. Corresponding formulas were also derived for the arch with hinged ends, but it was not thought worth while to give them.

Mr. Noetzli thinks it questionable whether the thick and flat arches of the lower part of a dam can be properly treated as arches. It all depends on whether the arch can withstand the tension at the intrados or the extrados for the loading assumed. If it can, then the structure acts as an arch for any central angle, however small; and, as previously shown, the formulas reduce to those for a straight beam, similarly loaded, when the central angle is made equal to zero. However, if the computed tension is greater than the material can withstand, then, as illustrated by Mr. Mensch in Fig. 5, another arch will be formed, with a much greater central angle, that can possibly withstand the stresses induced. The computation for the arch, Fig. 5, has been given by the writer in full; and, after the cracking, the results for the new arch are given in a foot-note. The computation for the new arch showed that it did not sustain any tension anywhere and that it could safely carry the load.

Mr. Noetzli states that the results obtained by the use of Figs. 4 and 5* of his paper, "The Relations Between Deflections and Stresses in Arch Dams," check almost exactly with those given by the writer. The figures furnished by the curves of Fig. 4 have not been examined by the writer, but those of Fig. 5 were carefully compared with corresponding figures obtained from Table 2 and the check was found to be satisfactory. Table 2 has been expanded into the more complete form, Table 6, and a corresponding diagram, Fig. 10, added.

In conclusion, the writer returns sincere thanks to those who have so kindly assisted in discussing his paper.

THE RELATION BETWEEN DEFLECTIONS AND STRESSES IN ARCH DAMS

By F. A. Noetzli,* Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Mensch, William Cain, B. F. Jakobsen, Charles P. Dunn, Albert B. Hill, L. Standish Hall, William A. Miller, Chauncy Wernecke, W. H. R. Nimmo, Gardner S. Williams and A. E. Greene, and F. A. Noetzli.

Synopsis

In this paper there is developed a method of calculating the stresses in arch dams, which result from the deformations and corresponding deflections of the arches, due to water pressure, change of temperature, shrinkage, lateral deformation, swelling, etc., provided the deflections of such arch dams have been measured or have been predetermined in some other way.

This method is based on the following fundamental principle: The deflection of an arch of known dimensions and material can be calculated by the elastic theory, if the stresses due to loads or other influences such as change of temperature, shrinkage, swelling, etc., are known. Consequently, if the deflections of the arch have been measured, the stresses which correspond to such deflections can be calculated in the opposite way.

The stresses which in an arch result from the shortening or lengthening of the arch axis, and the corresponding deflections, may be called "arch deflection stresses" to distinguish them from the direct axial stresses resulting from water pressure.

A few examples are given, which show the importance of the arch deflection stresses in some existing dams. These examples emphasize also the great desirability of measuring the deflections of all arch dams in order to indicate ways and means of designing future similar structures on a more economical and also on a safer basis.

Introduction

Although a great many slender arch dams have been built, which have proved beyond any doubt the great superiority of the arch over any other form

* Chf. Engr., Beckman and Linden Eng. Corporation, San Francisco, Calif.

of construction, very few tests have been made to determine the actual stresses and the factor of safety for such structures under different load and temperature conditions. This is all the more astonishing as the cylinder theory on which the design of most arch dams is based, is known to be defective in a great many ways. A comparison between theoretical and actual stresses, therefore, would have been very desirable, but, apparently, most designers were, or had to be, satisfied if the dams withstood successfully the water pressure. It is a fact that up to the present time no arch dam has failed, but this is hardly an excuse for neglecting the collection of data which would be of the greatest value for future constructions.

It is well known that arch dams are statically complicated structures, and any attempt toward a mathematically correct solution of this problem will result either in complicated computations, or it will be futile. With the present knowledge, this problem can be solved by approximations only, and many engineers are still in doubt in regard to the best and safest method of arch dam design. Furthermore, the assumptions on which the design of an arch dam has been based with regard to modulus of elasticity, range of temperature, influence of shrinkage, swelling, lateral expansion, etc., are still more or less uncertain, and can be standardized only by tests and extensive experiments.

These considerations show clearly the great desirability of having deflections and stresses of arch dams measured under different load and temperature conditions. In many other problems, for instance, in hydraulics for the flow of water in pipes, canals, and over weirs, etc., purely theoretical formulas fail, and resort has been had to experiments, whereby coefficients and other data can be determined, to amend the fundamental theory of flow in such a way as to make workable formulas available for all practical cases. In a similar manner, tests and experiments will be necessary to establish a standard method of arch dam design.

Present Theories Used for Arch Dam Design

Ordinary Cylinder Theory.—This is the earliest method of design and by it an arch dam is considered as a theoretical, free cylinder. For the purpose of design, every arch slice between two horizontal planes is considered as free to move relatively to other similar elementary arches.

This method of design of arch dams neglects entirely, first, that the lowest parts of a dam are practically immovable relative to the foundation, and that, consequently, no arching can take place, so that the water pressure at the bottom is resisted entirely by the weight of the dam (gravity or cantilever action); and, second, that the highest arches are stressed and forced to deflect, although theoretically they may not have to support any direct water pressure.

Theoretically, therefore, there are serious objections against designing arch dams by the cylinder formula alone. Nevertheless, it is a fact, that no arch dam has failed yet, and this, with the simplicity of the formula itself, is undoubtedly a strong argument in favor of the cylinder theory. However, arch dams of unprecedented magnitude are being contemplated for the near future. Also, there is a tendency to increase the unit stresses, and this increase may be justified only if the stresses in the arches are calculated more accurately than is possible by the simple cylinder theory.

Monolithic Cylinder Theory.—By this method* of design, an arch dam is considered to be a monolithic cylinder, fixed at the base and along the side-hills. This method, although theoretically as correct as can be expected for such a complicated case and for the assumptions made, is applicable only to some special cases, and its use, therefore, is limited.

Theory of Combined Cantilever and Arch Action.—This method† of designing arch dams is based on the assumption of combined cantilever (gravity) and arch action. By simple graphical constructions the division of the water pressure between vertical cantilever and horizontal arches may be obtained in any vertical section of the dam, that is, at the crown of the arch as well as nearer the side-hills. This method permits also of due consideration being given to shrinkage and temperature deformations, rib-shortening, swelling, lateral deformation (Poisson's ratio), etc., and the stresses resulting from these various influences can easily be determined and taken care of by reinforcement and a suitable distribution of the dam material.

Stresses in Arch Dams Determined from Deflection Measurements

It is a well recognized fact that a definite load acting on a structure produces a definite deflection, the size of which can be determined accurately if the theory of the structure and the basic assumptions underlying such theory are known. For instance, if an arch bridge is loaded with certain loads the deflections of the bridge due to such loads may be calculated by the theory of the elastic arch. On the other hand, if the deflections have been measured at a certain known temperature, the stresses in the material can be calculated with great accuracy, even if the load itself which produces the deflections is not accurately known.

Exactly the same reasoning applies to the relation between deflections and stresses in arch dams. If the load is known, the stresses and deflections may be calculated. If, on the other hand, the deflections have been measured, the stresses which produce such deflections can be determined by calculation. Deflections due to changes of temperature and those resulting from the shrinkage of concrete, etc., may be treated in a manner similar to that used for deflections due to direct loading.

Stresses which occur in the cantilevers, due to deformations and deflections along such beams in a dam, can be calculated by the well known theory of ordinary cantilever beams.

Stresses in the Horizontal Arch Slices Determined from the Arch Deflections

A number of measurements showing the deflections of arch crowns have been made for the Barren Jack Dam in Australia‡ and for the Salmon Creek Dam in Alaska.§ The deflection curves of these dams aroused considerable interest among engineers, but there seemed to be no way to derive any benefit

§ *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 319.

from these measurements for the future design and construction of similar structures.

As a matter of fact, these deflection curves are of the greatest interest and significance if interpreted mathematically. The method of combined cantilever and arch action provides a way of interpreting the real meaning and the natural consequence of such deflections, and permits of the calculation of the size of the stresses which were necessary to bend and deflect the structure in the manner shown by the deflection curves.

If the length of an arch is increased or decreased by any forces or influences, the arch crown is moved forward or backward accordingly. This produces bending moments if the span of the arch remains unchanged. Consequently, in addition to the axial compression stresses due to the water pressure, bending stresses also occur in an arch dam. For reservoir full, the arches may be considered to be fixed at the abutments; for reservoir empty, the degree of "fixity" is somewhat uncertain, unless the dam is anchored to the rock foundation by reinforcing steel bars.

Approximate Formulas for the Determination of Arch Deflection Stresses

It has been shown by the writer in a previous paper* that a change, ΔL, in the length, L, of an arch slice, 1 ft. thick, produces a horizontal thrust:

$$H = \frac{E \Delta L}{\int_{-\frac{l}{2}}^{+\frac{l}{2}} \frac{y^2 \, d L}{I}} = \frac{45 E I \Delta L}{4 h^2 l} = 0.94 \frac{E t^3}{h^2 l} \Delta L \text{ (approximately)} \ldots (1)$$

in which,

H = horizontal arch thrust acting at the distance of about one-third of the rise of the center line measured from the crown;

L = length of center line of arch;

ΔL = change of length, L, due to any cause, such as compression, shrinkage, temperature, etc.;

l = span of arch;

h = rise of arch;

I = moment of inertia of arch $= \frac{1}{12} t^3$;

y = ordinate of any point of the arch axis with regard to coordinates through one abutment of the arch;

t = thickness of arch slice;

E = modulus of elasticity.

For the derivation of Equation (1), deformations resulting from bending moments only were considered. This leads to fairly accurate results for thin arches of high rise. For thick and flat arches, however, the effect of direct and shearing stresses becomes very noticeable. The equation for the thrust, H, is then rather complicated. In analyzing a great number of arches of such dimen-

* "Gravity and Arch Action in Curved Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

sions, as they occur in general in arch dams, the writer has found that by considering direct stresses and shear, in addition to bending moments, a fairly accurate value of the total deformation thrust, H, may be obtained by Equation (1*a*):

$$H = 0.75 \frac{E t^3}{h^2 l} \Delta L \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1a)$$

The writer believes that for the sake of simplicity the use of Equation (1*a*) is justified in all average cases for which a maximum degree of accuracy is not of primary importance. Adequate means for determining the deformation thrust, H, more accurately, are given later.

The crown deflection, D, of an arch is given approximately by the equation*:

$$D = \frac{3}{16} \frac{L}{h} \Delta L \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

If, in an arch dam, the deflections, D, of the arches have been measured, it is possible to calculate also the corresponding variations, ΔL, of the length of the arch which caused the deflections, D.

Thus, from Equation (2),

$$\Delta L = \frac{16 h}{3 L} D \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Introducing Equation (3) in Equation (1),

$$H = 0.75 \frac{E t^3}{h^2 l} \frac{16 h}{3 L} D = \frac{4.0 E t^3}{h L l} D$$

For the arch slices in most arch dams, the length, L, of the arch does not differ greatly from the span, l, and, therefore,

$$H = 4.0 \frac{E}{L^2} \frac{t^3}{h} D$$

and because $\frac{L^2}{h} = 8.3 R$ (approximately),

$$H = 0.48 \frac{E}{R} \frac{t^3}{h^2} D \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

Thus, if the crown deflections, D, of an arch dam have been measured for a number of horizontal arch slices, the horizontal thrust, H, for each of these arch slices of a vertical thickness of 1 ft., is given in pounds by Equation (4) if all dimensions are measured in feet. H is to be taken as plus in the case of a lengthening of the arch, and minus in case of a shortening.

The thrust, H, which acts at a distance of practically one-third of the rise, h, from the arch crown, produces at any point of the arch a bending moment,

$$M = H \times \text{distance of point from the thrust, } H.$$

At the crown,

$$M = H \times \frac{h}{3} = 0.48 \frac{E}{R} \frac{t^3}{h^2} D \times \frac{h}{3} = 0.16 \frac{E}{R} \frac{t^3}{h} D \ldots\ldots\ldots (5)$$

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 11.

The thrust, H, and the moment, M, combined produce the stresses,

$$f_D = \frac{H}{t} \pm \frac{M}{\text{Sec. Mod.}} = 0.48 \frac{E}{R} \frac{t^3}{h^2} \frac{D}{t} \pm \frac{0.16 \frac{t^3}{h} \frac{E}{R} D}{\frac{1}{6} t^2}$$

$$f_D = 0.48\, D \frac{E}{R} \frac{t}{h} \left(\frac{t}{h} \pm 2 \right) \quad \ldots\ldots (6)$$

in which D is in feet and f_D is pounds per square foot.

If D is measured in inches and all the other dimensions are given in feet, Equation (6) may also be written in the form,

$$f_D = \frac{D}{25} \frac{E}{R} \frac{t}{h} \left(\frac{t}{h} \pm 2 \right) \quad \ldots\ldots (7)$$

The upper sign in Equations (6) and (7) gives the stresses, f_D, at the intrados, and the lower sign the stresses at the extrados if plus stands for compression and minus for tension. The deflection, D, is thereby to be considered plus for a deflection in an up-stream direction, and minus for a deflection in a down-stream direction.

In a fixed arch, the bending moments at the arch abutments resulting from the thrust, H, are approximately twice as large as at the crown, because the lever arm for H is about twice as long. The stresses are, therefore,

$$f_D = 0.48 \frac{t^3}{h^2} \frac{E}{t} \frac{D}{R} \pm \frac{2 \times 0.16 \frac{t^3}{h} \frac{E}{R} D}{\frac{1}{6} t^2}$$

$$f_D = 0.48\, D \frac{E}{R} \frac{t}{h} \left(\frac{t}{h} \pm 4 \right) \quad \ldots\ldots (8)$$

for D in feet, or,

$$f_D = \frac{D}{25} \frac{E}{R} \frac{t}{h} \left(\frac{t}{h} \pm 4 \right) \quad \ldots\ldots (9)$$

for D in inches.

The upper sign in Equations (8) and (9) gives the stresses, f_D, at the extrados and the lower sign the stresses at the intrados if plus stands for compression and minus for tension. The arch deflection, L, is again to be considered plus for a deflection in an up-stream direction and minus for a deflection in a down-stream direction.

As a general rule, it should be remembered that a lengthening of the arch axis (deflection in an up-stream direction) produces a positive thrust, H, and that a shortening of the arch axis (deflection in a down-stream direction) corresponds to a negative thrust, H. This "deflection thrust", H, which acts at a distance of about one-third of the rise of the arch from the crown, therefore, must not be confounded with the axial arch thrust from water pressure.

A deflection of an arch in an up-stream direction (deflection thrust, H, is plus) produces compression at the down-stream side near the crown and at the up-stream side near the abutments. At the same time, tension is produced at the up-stream side near the crown and at the down-stream side near the abutments.

A down-stream deflection (deflection thrust, H, is minus) produces tension at the down-stream side near the crown and at the up-stream side near the abutments, and, further, compression at the up-stream side near the crown and at the down-stream side near the arch abutments.

The arch deflection stresses in any horizontal dam slice for which the crown deflection, D, was measured, may be calculated, therefore, by Equation (6) or Equation (7) for a section at the crown and by Equation (8) or Equation (9) for the abutments. These deflection stresses have to be combined with the direct arch compression stresses from water pressure, in order to furnish the maximum stresses for the arch slice under investigation.

The deflection stress formulas, Equations (4), (6), (7), (8), and (9), should be applied with caution to very thick or flat arches, for which the ratio, $\left(\frac{l}{h}\right)$, is greater than, say, 0.8.

Stresses in the Vertical Cantilevers of Arch Dams

It has been shown previously that, particularly at the time of low dam temperature, practically all the water pressure near the base of arch dams is supported by pure cantilever action. In the upper parts of a dam horizontal arch action generally will prevail, but, nevertheless, the cantilever is forced to be bent and deflected by the respective movements of the arches. Such movements obviously introduce stresses of corresponding size in the cantilever. It is possible to calculate the size of these stresses if the deflections have been measured. The method of doing this is based on the well known theory of stresses and corresponding deflections in cantilever beams, and, therefore, will need no further explanation. A few illustrations, however, will be given in some examples discussed subsequently.

Statical Conditions of Existing Arch Dams

Most of the existing arch dams have been designed and built according to the ordinary cylinder theory. The fact that many of these dams have developed vertical cracks shows clearly that although pure arch action has been assumed in the design, temperature and shrinkage stresses are able at certain times to destroy such action entirely, because no arching can occur through open cracks.

If a reservoir formed by an unreinforced arch dam is empty, it has been shown by experience that in most such dams the opening of the vertical construction joints or other cracks is due to the shrinkage of the concrete during the setting and hardening of the cement and also to a decrease of temperature during the cold months of the year. Such a structure, before any water pressure acts on it, consists under those circumstances of a series of free vertical cantilevers.

Suppose, now, that the water rises slowly in the reservoir. At the beginning, its pressure will be supported entirely by the vertical cantilevers, because the contraction joints and other cracks are open, and it is evident that no arch stresses can be transmitted across open cracks. As soon as the cantilevers have deflected, under the pressure of the rising water, so far in a down-stream direction that all the vertical joints and cracks in the dam are closed, arching may occur and arch pressure is transmitted sidewise to the abutments. In

many existing arch dams, the water had to rise more than one-half the height of the dam before the vertical joints and cracks were closed. For instance, for the Salmon Creek Dam in Alaska, which is a constant-angle arch dam, 168 ft. high, the water had to rise about 110 ft. in the reservoir to be sufficient to keep the contraction joints closed.* In other words, when the water rose for the first time in the reservoir, this dam acted by pure vertical cantilever action until the water had reached a depth of slightly more than 100 ft. Then the contraction joints closed tightly under this pressure, and the arch stresses could aid in supporting the additional pressure when the water rose still higher.

Similar conditions exist for many other slender arch dams, and this is one of the reasons why such structures can be considered with very close approximation as a combination of vertical cantilevers and horizontal arches. Also, for structures which have not developed open vertical cracks visible to the eye, it is well known that contraction of the concrete occurs under the influence of shrinkage and low temperature just as it does in any other concrete structure. Good concrete may carry tension of from 100 to 200 lb. per sq. in., or develop a great number of hair cracks, particularly in reinforced structures. Such conditions again decidedly favor initial vertical cantilevering in the lower parts of such a dam, until either all these hair cracks are closed or the shrinkage tension in the arches is relieved so that actual arch compression can occur. To close the vertical hair cracks or to relieve such shrinkage tension as may exist in a horizontal direction in a dam, however, the vertical cantilever has first to be deflected a corresponding amount. This also shows clearly that in such a dam the water pressure near the base, of necessity, has to be supported almost entirely by vertical cantilever action.

It has been proposed to force grout into the contraction joints "and put initial axial compression into the whole structure, thereby making it act like a solid arch."† Such grouting if it could be extended uniformly all over a crack would be of great advantage indeed. However, serious objections have been voiced against the grouting of contraction joints. Such joints, or other cracks, as is well known, may be $\frac{1}{4}$ or $\frac{1}{8}$ in. wide in the upper parts of a dam, but diminish to nil at or slightly above the foundation. In the lower 50 ft. of a dam of a height of, say, 150 ft., the width of such open joints is, therefore, on an average probably less than $\frac{1}{12}$ or $\frac{1}{16}$ in., and it is more than doubtful whether such fine cracks can be filled evenly by cement grout which does not contain an excessive quantity of water. There exists, therefore, the great danger that large spaces in the joints will remain unfilled and that all the arch thrust due to the pressure of the rising water will be concentrated in those areas which were reached by the grout. This will often result, not only in an uneven distribution of the arch stresses, but also in large eccentricities of the arch thrust, thus producing heavy bending moments which ultimately may become a serious menace to the safety of such a dam.

On the other hand, if only a part of the cross-section of a dam is brought to carry the arch thrust, what help is to be expected from those parts of

* "Improving Arch Action in Arch Dams", by L. R. Jorgensen, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 320.

† *Loc. cit.*, p. 328.

the structure which lie opposite the unfilled spaces of the contraction joints? Here is the old problem of the case of a chain with some very strong and some rather weak links. If, however, it is recognized that the difficulties of filling contraction joints evenly with grout are practically insurmountable, how should it be possible, as is claimed, to fill these joints under such a pressure as to force the arch crown in an up-stream direction and to put shear on the foundation in the opposite direction to that due to the water load?* The pressure of the liquid grout can in no case be greater than the pressure due to the static head of this liquid, as in the case of any other vessel which is open at the top. The additional pressure shown by the grout pump is simply friction head of the grout flowing in the pipes and through the narrow cracks in the dam. Besides, there remain admittedly free air spaces in the joints, and it is difficult to imagine such air bubbles to be under considerable pressure while they could easily escape toward the open top.

Furthermore, an actual initial stress in the arches and a corresponding movement in the up-stream direction could only occur if the last contraction joint to be filled was widened to make possible the lengthening of the arch corresponding to the supposedly up-stream deflection. For instance, if a dam of the dimensions of the Salmon Creek Dam, referred to previously, should be grouted under such a pressure as to force the crown at the crest for, say, ½ in., in an up-stream direction, the contraction joint under pressure would have to be widened by more than ½ in. Of course, this would release at once the caulking material with which the down-stream side of the contraction joint was closed, and the grout would readily flow out.

It was deemed advisable to discuss somewhat at length the question of grouting the contraction joints of arch dams for the reason that important structures of this kind have been grouted in the past, and similar work is contemplated for the near future. For reasons already given, the grouting of contraction joints and other cracks is considered not only ineffective, as far as putting initial stresses into the arches is concerned, but, in certain cases, it may seriously affect the strength of an arch dam in which, for one reason or another, the joints have not been filled evenly. On the other hand, the construction joints of a straight gravity dam may be grouted with excellent results in order to make such joints water-tight.

A procedure which is undoubtedly much safer than grouting, consists of building or closing the arch during the colder season of the year. If this is not possible, for one reason or another, vertical slots of suitable width should be left during the construction and later filled during the colder season. In both cases, however, proper judgment must be used with regard to the closing temperature, in order that the arches and the cantilever are not over-stressed at the time the arch temperature rises to the seasonal maximum and when the reservoir is empty.

EXAMPLES

Practically all existing arch dams, with the exception of the Wooling Dam in Australia, have been designed and built according to the ordinary cylinder

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 326.

theory. As far as the writer knows, the Wooling Dam is the only structure of its kind designed as a monolithic cylinder fixed at the base. The deflections of this dam were measured and a close coincidence between calculated and measured deflections was found, so that the correctness of the monolithic cylinder theory as applied to this dam seems to be established beyond any doubt.

The writer's graphical method of investigating arch dams by considering such structures as acting like a combination of vertical cantilevers and horizontal arches has been proved* to give results which check almost exactly with those obtained by the mathematically correct method given by B. A. Smith, M. Am. Soc. C. E.† Thus, also, the soundness of the theory of combined cantilever and arch action is established, at least with this example. It may be of interest, therefore, to apply those principles to some other dams for which deflections have been measured.

The Barren Jack Dam in Australia.—This is an arch dam of a maximum height of 42 ft. above bed-rock, the radius of the up-stream face being 80 ft. The dam is 5.0 ft. thick at the base and 2.0 ft. thick at the crest. Fig. 1 shows a cross-section and various deflection curves for the arch crown under different load and temperature conditions.

A striking feature of the deflection lines is the comparatively large angle at the foundation between the deflection curves and the line of zero deflection. Undoubtedly, the curves drawn through the various observed points have their origin at one common point at the foundation base. This point of origin, of course, is practically the same for any load and corresponding deflection curves for the simple reason that the bed-rock prevents any appreciable movement of the base of the dam. Elastic deformations are in some ways proportional to the unit stresses in the material, and the unit stresses in the large masses of bed-rock, resulting from the shearing and bending forces exerted by the dam on the rock, are so small at a short distance below the plane of contact between dam and bed-rock that the corresponding elastic deformations of the bed-rock itself are negligible. Any investigation of the bed-rock deformations at the base of any of the existing arch dams will prove this beyond any doubt.

Consequently, it follows that if the bed-rock is not deformed elastically, or in any other manner, for any appreciable amount, the dam may be considered to be rigidly fixed at the base unless cracks should have developed either between the masonry and the rock or in the masonry itself at the time when the dam came under pressure and was deflected more than is elastically possible.

Consider, now, a vertical dam slice at the crown of the arches where the deflections were measured. If such a cantilever was rigidly fixed at the base, either due to its own weight or to special anchorage to the bed-rock, any deflection line would have the original line of zero deflection as a tangent at the origin at the base. The deflection curves of the Barren Jack Dam show a marked angle at the origin between the line of zero deflection and the

* Discussion on "Gravity and Arch Action in Curved Dams", by William Cain, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 71.

† *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 2027.

deflection curve itself. For instance, the measurements of August 10th, 1909 (Fig. 1), gave the deflection of a point 12 ft. above the base as 0.25 in., and the angle, α, between the deflection line on that date and the line of zero deflection is given by the relation,

$$\tan \alpha = \frac{0.25}{12 \times 12} = 0.00173$$

whence,

$$\alpha = 0^\circ\ 05'\ 58''$$

Such a large angle can only be explained by deformations far beyond elastic ones, or, in other words, by open cracks either between the dam and the foundation or a short distance above the foundation in the masonry itself. That such open cracks may occur due to over-stressing the cantilever, has been indicated previously by other calculations.* The deflection curves of the Barren Jack Dam undoubtedly prove that such a break has occurred in this structure. The maximum arch deflection at the crest was found to be 0.58 in. (May 25th, 1909).

By Equation (7), substituting

$D = -0.58$ in. (down stream, therefore, D, is negative);
$E = 2\,500\,000$ lb. per sq. in. (assumed);
$R = 79$ ft.;
$t = 2$ ft.;
$h = 24$ ft., (estimated);

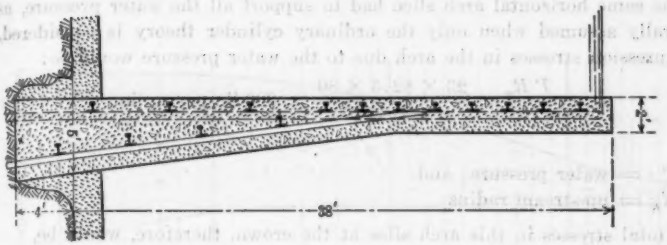
we obtain the stresses in the arch crown resulting from the deflection, as follows:

$$f_D = \frac{D}{25}\frac{E}{R}\frac{t}{h}\left(\frac{t}{h} \pm 2\right) = \frac{-0.58}{25}\frac{2\,500\,000}{79}\frac{2}{24}\left(\frac{2}{24} \pm 2\right)$$

$$f_D = \begin{cases} -127 \text{ lb. per sq. in. (tension) intrados;} \\ +117 \text{ lb. per sq. in. (compression) extrados.} \end{cases}$$

On August 10th, 1909, the deflection of the Barren Jack Dam at an elevation of 17 ft. above the base was found to be 0.36 in. (Fig. 1).

By Equation (7), substituting



$D = -0.36$ in. (down stream);
$E = 2\,500\,000$ lb. per sq. in.;
$R = 78$ ft.;
$t = 4$ ft.;
$h = 10$ ft. (estimated);

we obtain for the arch deflection stresses at the crown,

$$f_D = \frac{-0.36}{25}\frac{2\,500\,000}{78}\frac{4}{10}\left(\frac{4}{10} \pm 2\right)$$

$$f_D = \begin{cases} -442 \text{ lb. per sq. in. (tension) intrados;} \\ +295 \text{ lb. per sq. in. (compression) extrados.} \end{cases}$$

FIG. 1.

If the same horizontal arch slice had to support all the water pressure, as is generally assumed when only the ordinary cylinder theory is considered, the compression stresses in the arch due to the water pressure would be:

$$f_w = \frac{P R_u}{t} = \frac{23 \times 62.5 \times 80}{4 \times 144} = 200 \text{ lb. per sq. in.}$$

where

P = water pressure; and,
R_u = up-stream radius

The total stresses in this arch slice at the crown, therefore, would be,

$$f_D = \begin{cases} -242 \text{ lb. per sq. in. (tension) intrados;} \\ +495 \text{ lb. per sq. in. (compression) extrados.} \end{cases}$$

Due to the cantilever action which undoubtedly helps in supporting the water pressure at this elevation, the direct arch stresses are reduced somewhat. The correct values could be obtained by applying the method of combined cantilever action and horizontal arching.

In a similar manner, as shown previously, the arch deflection stresses and the maximum stresses may be determined at other elevations for any horizontal arch slice and for any characteristic load and deflection in an up-stream or down-stream direction.

It is needless to say that in a scientifically designed arch dam all excessive tension stresses should be taken care of by sufficient steel reinforcement to prevent the occurrence of tension cracks.

The Salmon Creek Dam in Alaska.—The Salmon Creek Dam, near Juneau, Alaska, is the first dam designed and built according to the modern principles of the constant-angle or varying radius types. The deflections of this structure were measured on a number of days when the water in the reservoir stood at different elevations and when the dam temperature had varied considerably from the normal.

The deflection curves of this dam have been published and discussed by L. R. Jorgensen, M. Am. Soc. C. E., in his paper, entitled "Improving Arch Action in Arch Dams".* A further interpretation of these deflections, based on the method of combined vertical cantilever and horizontal arch action, will be given by the writer. It is believed that certain phenomena occurring in the deflections of this dam and not clearly recognized heretofore may be more easily understood in this way. For the sake of convenience, the deflection curves of the Salmon Creek Dam are reproduced in Fig. 2.

The dotted line, *O-A-B*, in Fig. 2, shows the theoretical deflections of the arches for full water pressure and by neglecting cantilever action (simple-cylinder theory), it is evident that the theoretical and the actual deflections do not coincide with each other.

A slight modification in the measured deflection curves has been made in Fig. 2, in that the dotted lower portions of the lines have been brought to a common origin. For reasons explained in more detail in connection with the example of the Barren Jack Dam (page 293), it is believed that the large masses of solid bed-rock into which the base of the dam was keyed, did not deform

appreciably under the stresses exerted by the dam, at least not so much as to enable such elastic down-stream deformation to be measured and to be shown on the diagram.

The most striking feature of the deflection lines of this dam is again, as in the case of the Barren Jack Dam, the large angle at the base between the deflection curves and the line of zero deflection. This phenomenon is expressed most decidedly for the deflections measured on October 27th, 1915 (Curve No. 7). At Elevation 1035 (28 ft. above the base), the deflection measured on that day was found to be 0.375 in.

The angle, α, is given by the relation,

$$\tan \alpha = \frac{0.375}{28 \times 12} = 0.00111$$

and,

$$\alpha = 0^\circ\ 03'\ 50''$$

A cantilever fixed at the base and deflected elastically by loads above could not form such a large angle at the base, but would have the line of zero deflections as a tangent, approximately as shown by a typical cantilever deflection curve in Fig. 2.

In view of the fact that the deflections of the Salmon Creek Dam show clearly a large angle between the deflection curves and the line of zero deflection, it is evident that one or a series of cracks have opened in the cantilever on the up-stream side of this structure. These cracks may have occurred either between the dam and the bed-rock or in the masonry itself a short distance above the bed-rock, wherever the least tensile strength existed. Such cracks, of course, will extend only for a comparatively short distance into the dam body, and the water-tightness is insured sufficiently by the increased compression stresses near the down-stream side.

A further proof that this dam has developed horizontal cracks at the up-stream side is shown by the following calculation:

Consider a vertical cantilever slice at the center of the dam, where the deflections have been measured. The measurements of October 27th, 1915 (Curve No. 7), shows the deflection of this cantilever to have been 0.375 in. at a distance of 28 ft. above the base. Neglect, now, for the purpose of this investigation, the portions of the vertical cantilever above Elevation 28. There remains, then, a cantilever of, say, a lateral width of 1 ft. and a depth equal to the thickness of the dam, or, on an average, about 42 ft. in this particular case. The length of this cantilever is 28 ft. and the deflection of the upper end, that is, 28 ft. from the fixed end at the base, has been measured at 0.375 in. (Fig. 3).

In order to deflect such a cantilever for 0.375 in., a uniformly distributed load of about

$$W = 20\,000\,000 \text{ lb.}$$

would be necessary. The bending moment at the fixed end would then be,

$$M = 20\,000\,000 \times \frac{28}{2} = 280\,000\,000 \text{ ft-lb.},$$

producing stresses of,

$$f = \pm \frac{M}{\text{Sec. Mod.}} = \pm \frac{280\,000\,000}{\frac{1}{6} \times 1 \times 42^2} = \pm 950\,000 \text{ lb. per sq. ft.}$$

which, of course, is impossible. Even after consideration of the weight of the cantilever, and all other forces and reactions transmitted from the upper parts of the dam to the short cantilever under investigation, it is clearly seen that such a short and deep cantilever cannot deflect for 0.375 in. without cracking or being partly lifted from the "fixed" end. It is also impossible that the well-seasoned concrete at the base should have "flowed" so much as to permit such a large deflection before the limit of tensile strength of the concrete was reached at the up-stream side.

These mathematical interpretations of the deflections of the Salmon Creek Dam seem to be conclusive proof that this structure broke away partly from the base and developed horizontal cracks at the up-stream side at a time when the water in the reservoir had risen toward the crest and the dam temperature was low.

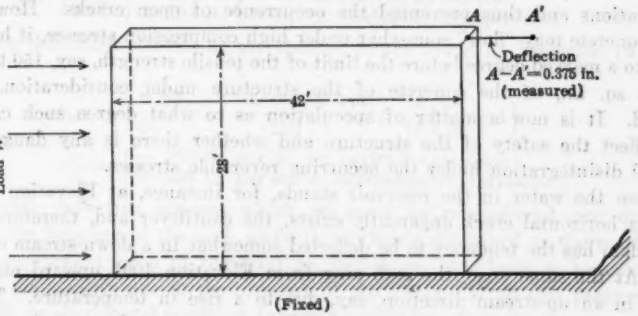

FIG. 3.

Another matter of great interest is the "knee" in the deflection lines at Elevation 1095. This irregularity in the deflections was explained by the fact that the concrete near Elevation 1095 was poured during a period of low temperature (end of construction season). Curve No. 7, Fig. 2, shows the maximum bend in the knee between Elevations 1075 and 1115 to be about 0.18 in.

Any calculations for determining the deflection of a concrete beam, 40 ft. long and 28 ft. deep, will show that a deflection as large as 0.18 in. at the center is impossible for an unreinforced beam of these dimensions without producing cracks. For instance, in order to bend a concrete beam, 40 ft. long, 28 ft. deep, and 1 ft. wide, for 0.18 in. at the center, theoretically, a load of about 9 500 000 lb., uniformly distributed, would be required, producing a maximum tension of more than 2 500 lb. per sq. in. Such is, of course, impossible.

Similar reasoning leads to the conclusion that there may be another horizontal crack in the dam near Elevation 1155. The measurements made on May 18th, 1915 (Curve No. 4, Fig. 2), show that below Elevation 1155

the deflection line was nearly vertical for about 40 ft. and that, at the crest, the dam deflected about 0.17 in. relatively to Elevation 1155. A short calculation for the cantilever portion above Elevation 1155 shows that, even under conservative assumptions, this cantilever, 20 ft. long, with an average thickness of about 8 ft., would have to sustain tensile stresses of more than 900 lb. per sq. in., in order to allow a deflection of 0.17 in. at the free end. This seems to indicate that probably another horizontal break has occurred at or near Elevation 1155, as stated.

The deflection curves of the Salmon Creek Dam, therefore, lead to the conclusion that in this structure the vertical cantilever is broken at three different elevations. The breaks occurred most probably in horizontal construction joints where new concrete was poured on top of the old, or where the accumulation of laitence had reduced the tensile strength. Although the deflection curves clearly indicate the presence of cracks, nothing can be predicted, of course, with regard to their number, width, and extension, without deflection measurements being taken at other points of the dam. It may be argued that the concrete of the dam "flowed" in excess of the elastic deformations and thus prevented the occurrence of open cracks. However, while concrete may "flow" somewhat under high compression stresses, it hardly did so to a marked degree before the limit of the tensile strength, say, 150 to 200 lb. per sq. in., of the concrete of the structure under consideration, was reached. It is now a matter of speculation as to what degree such cracks may affect the safety of the structure and whether there is any danger of gradual disintegration under the occurring reversible stresses.

When the water in the reservoir stands, for instance, at Elevation 1095, where a horizontal crack apparently exists, the cantilever and, therefore, the whole dam has the tendency to be deflected somewhat in a down-stream direction. At the same time, the arch ring from Elevation 1095 upward may be forced in an up-stream direction, say, due to a rise in temperature. Thus, shearing stresses of considerable magnitude occur in the plane of the crack, and this fact may lead to a movement and to progressive deterioration, if the climatic conditions are such as to favor deflections in opposite directions.

It may now be of interest to calculate also the "arch deflection stresses" in the horizontal dam slices.

The maximum deflection of the highest arch, as measured on October 27th, 1915, was 0.98 in. (Curve No. 7, Fig. 2). As a matter of fact, it must have been somewhat larger, because the assumed line of zero deflection (Curve No. 1) includes already the deflection necessary to close the open cracks in the dam.*

By Equation (7), substituting

$D = -0.98$ in. (down stream);
$E = 2\,500\,000$ lb. per sq. in.;
$R = 325$ ft.;†
$t = 6$ ft.;†
$h = 150$ ft.;†

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 320.

† These dimensions are taken from Plate XIII, *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 709.

we obtain the stresses at the arch crown resulting from the deflection, as follows:

$$f_D = \frac{-0.98}{25} \times \frac{2\,500\,000 \times 144}{335} \times \frac{6}{150}\left(\frac{6}{150} \pm 2\right)$$

$$f_D = \begin{cases} -24 \text{ lb. per sq. in. (tension) intrados;} \\ +23 \text{ lb. per sq. in. (compression) extrados.} \end{cases}$$

On the same day, the deflection of the dam was 0.82 in. at an elevation of 108 ft. above the base (Curve No. 7, Fig. 2). At this elevation,

$$R = 282 \text{ ft.};$$
$$t = 24 \text{ ft.};$$
$$h = 76 \text{ ft.}$$

Then, by Equation (7), the arch deflection stresses at the crown of this arch slice are,

$$f_D = \frac{-0.82}{25} \times \frac{2\,500\,000 \times 144}{282} \times \frac{24}{76}\left(\frac{24}{76} \pm 2\right)$$

$$f_D = \begin{cases} -213 \text{ lb. per sq. in. (intrados) tension;} \\ +154 \text{ lb. per sq. in. (extrados) compression.} \end{cases}$$

The arch deflection stresses at the abutments are found by Equation (9), as follows:

$$f_D = \frac{-0.82}{25} \times \frac{2\,500\,000 \times 144}{282} \times \frac{24}{76}\left(\frac{24}{76} \pm 4\right)$$

$$f_D = \begin{cases} -396 \text{ lb. per sq. in. (extrados) tension;} \\ +338 \text{ lb. per sq. in. (intrados) compression.} \end{cases}$$

These arch deflection stresses which, as must be remembered, are due entirely to the bending of the arch while it was being shortened as the result of axial compression, drop of temperature, shrinkage, etc., have to be combined with the stresses due to the pressure of the water. If all this pressure was carried by horizontal arching (ordinary cylinder theory), the stresses from water pressure in the arch investigated would be:

$$f_w = \frac{58 \times 62.5 \times 294}{24} = +307 \text{ lb. per sq. in. (compression).}$$

This stress combined with the arch deflection stresses gives the maximum unit stresses in this arch slice, as follows:

At the crown..... { Intrados $f_{max.} = +94$ lb. per sq. in. (compression);
Extrados $f_{max.} = +461$ lb. per sq. in. (compression).

At the abutments.. { Extrados $f_{max.} = -89$ lb. per sq. in. (tension);
Intrados $f_{max.} = +645$ lb. per sq. in. (compression).

In this manner, the arch deflection stresses and the corresponding maximum stresses in the arching parts of this dam may be determined at any other elevation and for any load and temperature condition for which deflection measurements are available, or may be made any time in the future.

The calculations point to a maximum compression at the intrados near the abutments of slightly more than 600 lb. per sq. in. It is possible that under such high unit stresses the green concrete "flowed" somewhat so that a re-adjustment took place, which reduced the theoretical unit stresses both

on the tension and on the compression side. Such a "flow" could be best detected by continuous deflection measurements at various critical places on the dam. Furthermore, it has to be considered that whenever, in an unreinforced arch dam, cracks have opened on the tension side, the theoretical maximum compression stresses are also reduced, because the resultant of the compression stresses in such a case has to equal the compression resulting from the external loads.

More Accurate Formulas for the Determination of the Arch Deflection Stresses

As previously mentioned, Equations (6), (7), (8), and (9), are only approximations, their main advantage being their simplicity. Greater accuracy is obtained by taking into consideration, in a theoretically correct manner, also the deformations due to the axial stresses and the shearing stresses, in addition to those resulting from bending moments.

The elastic theory of arches, as given in most modern treatises on arch design, shows the horizontal arch thrust, H_f, which is due to rib-shortening resulting from loads applied to the arch, to be:

$$H_f = - \frac{H_a \int \frac{d\,L}{A}}{\int y^2 \frac{d\,L}{I} + \int \cos^2 \alpha \frac{d\,L}{A} + 3 \int \sin^2 \alpha \frac{d\,L}{A}} \quad \ldots\ldots (10)^*$$

whereby, in the case of a horizontal slice of an arch dam, 1 ft. thick:

H_f = arch thrust resulting from rib-shortening;
H_a = arch thrust due to the water pressure;
$d\,L$ = length of an arch element;
A = cross-section of arch (= thickness, t, of arch slice);
y = ordinate of arch elements, $d\,L$, with regard to a horizontal X-axis drawn through the center of gravity of the whole arch;
α = angle of inclination between arch element and horizontal X-axis; and
I = moment of inertia of cross-section of arch $\left(I = \frac{1}{12} t^3\right)$.

According to Hooke's law, H_a has the value:

$$H_a = \frac{\Delta\,L}{L} E\,t$$

where E equals the modulus of elasticity and $\Delta\,L$ equals the total shortening of the arch axis. Further, there is,

$$\int \frac{dL}{A} = \frac{L}{t}$$

The numerator of Equation (10) is, therefore, $E\,\Delta\,L$.

The first term in the denominator of Equation (10), for H_f, that is, $\int y^2 \frac{d\,L}{I}$, represents the influence from bending moments; the second term,

* Equation (10) should not be used for arches with central angles of more than, say, 120 degrees.

$\int \cos^2 \alpha \frac{d\,L}{A}$, gives the influence of the direct stresses; and the third term, $3 \int \sin^2 \alpha \frac{d\,L}{A}$, represents the influence from shearing stresses.

The main term in the denominator of Equation (10) is $\int y^2 \frac{d\,L}{I}$, and, as shown in the writer's paper, "Gravity and Arch Action in Curved Dams",* this equals very nearly $\frac{4\,h^2\,l}{45\,I}$. Consequently, H_f has approximately the value,

$$H_f = 0.94 \frac{E\,t^3}{h^2\,l}\,\Delta\,L$$

which is the same as that obtained in Equation (1).

In order to obtain a more accurate value of H_f, we will compare its value (Equation (10)) with the approximate value given by Equation (19 *a*) of the writer's paper, "Gravity and Arch Action in Curved Dams"*. Equation (10) may be written:

$$H_f = -\frac{H_a \int \frac{d\,L}{t}}{\int y^2 \frac{d\,L}{I} + \int \cos^2 \alpha \frac{d\,L}{t} + 3 \int \sin^2 \alpha \frac{d\,L}{t}} \quad \ldots\ldots (11)$$

Equation (19*a*) of the writer's paper,* previously mentioned, reads:

$$H_f = -0.94\,f'_c \frac{t^3}{h^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

in which f'_c equals the axial stress due to water pressure. The thrust, H_a, in Equation (11) equals $f'_c\,t$, and the whole numerator, therefore, has the value, $f'_c\,L$.

In order to make H_f in Equation (12) equal to the more correct value of H_f in Equation (11), one simply has to introduce in Equation (12), instead of the approximate constant value, 0.94, such a factor, k_f, that Equation (12) furnishes the same values for H_f as Equation (11).

The factor, k_f, may be calculated from the relation:

$$H_f = -\frac{f'_c\,L}{\int y^2 \frac{d\,L}{I} + \int \cos^2 \alpha \frac{d\,L}{t} + 3 \int \sin^2 \alpha \frac{d\,L}{t}} = -k_f\,f'_c \frac{t^3}{h^2}$$

from which,

$$k_f = \frac{h^2\,L}{t^3 \left(\int y^2 \frac{d\,L}{I} + \int \cos^2 \alpha \frac{d\,L}{t} + 3 \int \sin^2 \alpha \frac{d\,L}{t} \right)} \quad \ldots\ldots (13)$$

The values, k_f, have been calculated for arches with central angles of from 60 to 180° and for various proportions of $\left(\frac{t}{h}\right)$, which are plotted in Fig. 4.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

The arch thrust, H_f, which is due to rib-shortening, may be calculated, therefore, for any arch slice of an arch dam from the following equation:

$$H_f = -k_f f'_c \frac{t^3}{h^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

whereby k_f may be taken from Fig. 4 for the different central angles of the arches and the various proportions of $\left(\frac{t}{h}\right)$.

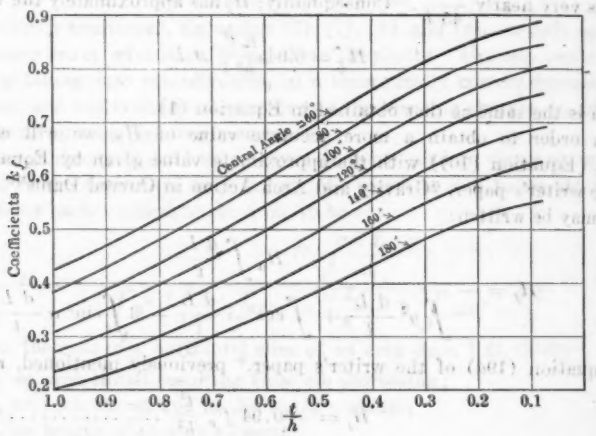

FIG. 4.

The arch thrust, H_f, which acts, as should be remembered, at a distance of approximately one-third of the rise of the arch from the crown, produces bending moments and stresses in the arch. For instance, at the crown, the stresses due to H_f are:

$$f_c = \frac{H_f}{t} \pm \frac{H_f \frac{h}{3}}{\text{Sec. Mod.}}$$

$$f_c = -k_f f'_c \frac{t}{h}\left(\frac{t}{h} \pm 2\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (15)$$

in which, f_c is pounds per square foot; and at the abutments:

$$f_c = \frac{H_f}{t} \pm \frac{H_f \frac{2}{3} h}{\text{Sec. Mod.}}$$

$$f_c = -k_f f'_c \frac{t}{h}\left(\frac{t}{h} \pm 4\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

The deformations resulting from temperature and shrinkage have to be treated separately from those due to rib-shortening.

For temperature deformations, the theory of the elastic arch gives the horizontal thrust:

$$H_t = \frac{c\,T\,l}{\int y^2 \frac{d\,L}{I} + \int \frac{d\,L}{A}} \qquad (17)$$

in which,

c = coefficient of expansion;
T = change of arch temperature;
l = span of arch.

In a manner similar to Equation (14) for H_f, Equation (17) for H_t, may be transformed into:

$$H_t = k_t\,E\,c\,T\frac{t^3}{h^2} \qquad (18)$$

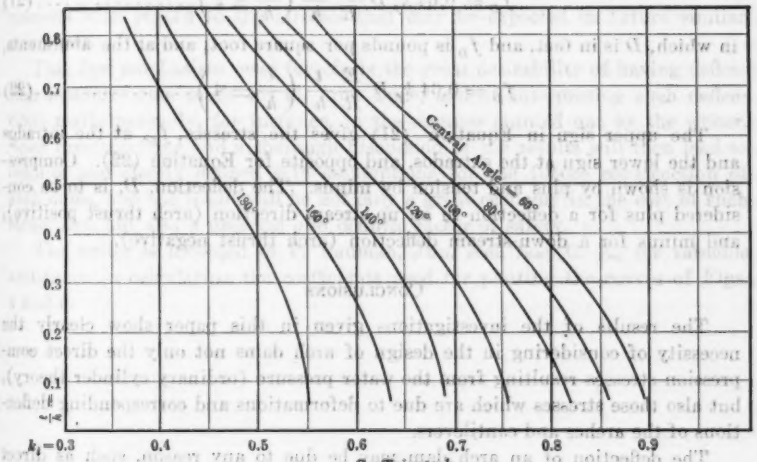

FIG. 5.

The numerical values for k_t are calculated and plotted in Fig. 5 for different central angles between 60 and 180° and for various values of $\frac{t}{h}$.

The stresses in the arch due to H_t are, at the crown,

$$f_c = k_t\,E\,c\,T\frac{t}{h}\left(\frac{t}{h} \pm 2\right) \qquad (19)$$

in which, f_c is pounds per square foot; and at the abutments,

$$f_c = k_t\,E\,c\,T\frac{t}{h}\left(\frac{t}{h} \pm 4\right) \qquad (20)$$

If the deflections, D, of an arch dam have been measured, and it is desired to know the resulting arch deflection stresses, the procedure is as

follows: Insert in Equation (14) for f'_c (axial stress due to water pressure), its value (Hooke's law):

$$f'_c = \frac{\Delta L}{L} E$$

Then,

$$H_f = k_f \frac{E t^3}{h^2 L} \Delta L$$

Introduce for ΔL its value according to Equation (3),

$$\Delta L = \frac{16 h}{3 E} D$$

The deformation stresses in the arch may then be obtained in a manner similar to that previously shown. At the crown,

$$f_D = 0.64 k_f D \frac{E}{R} \frac{t}{h} \left(\frac{t}{h} \pm 2 \right) \ldots\ldots\ldots\ldots\ldots (21)$$

in which, D is in feet, and f_D is pounds per square foot; and at the abutments,

$$f_D = 0.64 k_f D \frac{E}{R} \frac{t}{h} \left(\frac{t}{h} \pm 4 \right) \ldots\ldots\ldots\ldots\ldots (22)$$

The upper sign in Equation (21) gives the stresses, f_D, at the intrados and the lower sign at the extrados, and opposite for Equation (22). Compression is shown by plus and tension by minus. The deflection, D, is to be considered plus for a deflection in an up-stream direction (arch thrust positive), and minus for a down-stream deflection (arch thrust negative).

Conclusions

The results of the investigations given in this paper show clearly the necessity of considering in the design of arch dams not only the direct compression stresses resulting from the water pressure (ordinary cylinder theory), but also those stresses which are due to deformations and corresponding deflections of the arches and cantilevers.

The deflection of an arch dam may be due to any reason, such as direct water pressure, temperature, shrinkage, swelling, lateral deformation (Poisson's ratio), etc., or a combination of any or all of them. The fact that such deflections have been measured enables the determination of the resulting arch deflection stresses, by the aid of the formulas given, with a fair degree of accuracy.

It has been claimed recently that whenever it takes a comparatively long time, say, 14 days or more, to develop the full load in a concrete dam, the stresses, under such circumstances, would be greatly reduced due to the so-called "time factor". It is a fact borne out by tests that "green" concrete, and, to a certain degree, also, older concrete, deforms under high compression stresses somewhat more than the assumed laws of true elasticity would permit. Such test results, however, which were made under conditions absolutely strange to what ordinarily is the rule for arch dams, can hardly be applied directly to dam construction, and, as far as the writer knows, they also are not considered in any other practical design of concrete structures. As a matter

of fact, experience has shown that in dam construction, in an unmistakable manner, the "time factor" is of negligible influence as long as the unit stresses are low, inasmuch as it is not even able to prevent the very slowly working shrinkage deformations from cracking the concrete. It is the writer's opinion that for these reasons the "time factor" should not be considered in the design of arch dams, as long as the stresses are kept below a reasonable limit.

The foregoing deflection-stress formulas may be of value also for the design of new arch dams. It is possible in many cases to predetermine the probable deflections of a dam designed as a "cantilever arch dam" by the method of combined cantilever and arch action. Consequently, the "arch deflection stresses" in such a structure may also be predetermined with a fair degree of accuracy. On the other hand, those formulas will enable an approximate determination to be made of the stresses in the arches of existing dams if the deflections are measured. This will then permit engineers to judge the factor of safety of such dams and, also, to draw conclusions with regard to the stresses that may be expected in future similar structures.

This fact emphasizes most forcefully the great desirability of having deflection measurements made for all arch dams, and of interpreting such deflections mathematically, for instance, in the manner pointed out by the writer. Such investigations and a thorough discussion of the results will then lead to definite and closely defined safe assumptions for the future construction of arch dams, and the result will be not only a great economy in the cost of such structures, but also a uniform and definite factor of safety.

The writer is indebted to P. Bauman, Jun. Am. Soc. C. E., for valuable assistance in calculating the coefficients used for plotting the curves of Figs. 4 and 5.

DISCUSSION

L. J. MENSCH,* M. AM. SOC. C. E. (by letter).—During a recent visit to the Pacific Coast, the writer was greatly impressed by the great importance of dams to the prosperity of the western part of the United States. For irrigation, power development, and flood control, dams of enormous heights are proposed, among which may be mentioned the Pacoima Creek Dam, in the San Fernando Valley, north of Los Angeles, 375 ft. high, the St. Gabriel Dam, 15 miles west of Los Angeles, 420 ft. high, and the gigantic Boulder Canyon Dam of the Colorado River, with a height above bed-rock of 730 ft., about 200 ft. long at the base, and 1 000 ft. long at the crest. The sparsely settled West can hardly afford gravity dams of these great dimensions.

Water and power have always been absolute necessities for the development of the West and capital has been scarce, therefore, new types of dams came into vogue, which would have been out of the question in more settled countries. Such dams are the rock-fill dam, the hydraulic-fill dam, the multiple-arch dam, and the single-arch dam (notably represented by the Bear Valley Dam built in 1884 and the Upper Otay Dam built in 1900, both unsurpassed for economy by any other dam, or for safety by few gravity dams). When it is considered that such a simple problem as the design of a gravity dam required more than 100 years of experience and many important failures before it was partly solved so that engineers agreed fairly well as to the main features of the design, the fact that the design of new types of dams is not free from many imperfections need not cause much surprise. These dams are usually designed by hydraulic engineers who have their own particular problems to develop and who, as a rule, have not the time, inclination, nor experience and perception, not to speak of the important knowledge of the literature on the subject, to delve into the intricacies of strange and difficult structural problems.

Engineers trained in structural design look with wonderment, and also with suspicion, at the apparently crude principles by which most of these dams have been designed, and Mr. Noetzli's paper may be considered as a plea against dam design which is not based on strictly structural lines, and more especially against the practice of designing single-arch dams on the principle of a thin cylinder. Scientific principles of the co-related problem of the design of cylindrical tank walls where they join the bottom were published many years ago. Grashof treats of it in Paragraphs 203 to 210 of his book.† A graphical solution is given by Dr. von Emperger‡ for a tank 130 ft. in diameter and 28 ft. high. A very good and simple approximate solution is given on page 257 of *Beton und Eisen* for 1907. Professor Reissner has given a more rigorous treatment of the subject,§ which is nearly identical with the solution presented to the Society twelve years later by B. A. Smith, M. Am. Soc. C. E.‖ Since then, at least a dozen articles on the same subject have appeared in *Beton und Eisen*. An approximate solution was published in *Engineering and*

* Gen. Contr., Chicago, Ill.

‖ *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 2027.

Contracting in 1912 for a tank built by the writer in Penetanguishine, Ont., Canada.

That large tanks, built of masonry or even of steel, which are not designed for the restraint of the walls at the bottom, are not satisfactory may be shown by the collapse of a large molasses tank in Boston, Mass., a few years ago, and the trouble caused by cracks in concrete tanks where the walls join the bottom. A serious case came to the writer's attention some time ago. A certain Middle Western town contracted for two reinforced concrete tanks 150 ft. in diameter and 24 ft. high. The wall was 24 in. thick at the bottom and was keyed into a recess of the foundation. After the first tank was finished, water was admitted, but the wall sheared off the key and, besides, cracked the floor of the tank near the wall. On the writer's advice a number of circumferential bars near the bottom were omitted in the construction of the second tank, and cut up into shorter bars which served as reinforcement of the joint between the wall and the bottom to take up the cantilever moment at the base. The second tank, although built by the same contractor, was tight from the first filling.

The writer attempted to use the same theory for the design of single-arch dams, and was surprised to find that according to this theory nearly all existing arch dams ought to show serious defects. Although a few such dams in Australia have shown some vertical and horizontal cracks, they evidently are not serious, and few cracks except those which may be ascribed to temperature action have been reported on dams built in the United States. No considerable leakage at the bottom, like that so often observed in reinforced concrete tanks where the walls are not properly tied to the bottom, have been reported for any arch dam; on the contrary, many arch dams are absolutely dry on the down-stream side.

The author's praiseworthy efforts to solve the problem failed, in the writer's opinion, because he tried to solve only that part which has been understood fairly well by structural engineers and which, as has been stated, does not explain the well known safety of arch dams. He tried to explain the arch action by the theory of the thin parabolic arch of small rise, although every textbook containing this theory warns the student not to use it in case of thick arches or arches of considerable rise. Serious discrepancies having been called to his attention in the discussion of his first paper,* he tried to improve his theory by using the formulas of a thick parabolic arch with small rise, which is not sufficiently accurate for the lower arches of a dam. In his excellent paper on thick circular arches† Professor Cain has shown that Mr. Noetzli's formula for deflection is not reliable for flat arches, and the writer can affirm that the curve in Fig. 4 for the 180° arches gives values at least 50% too great and the other curves are in error in proportion. In the upper part of a dam, the secondary stresses are comparatively small and, for that part, the author's formulas give workable results.

How untenable the author's approximate theory is, will be illustrated by the example he chose, the Salmon Creek Dam, designed by L. R. Jorgensen,

* "Gravity and Arch Action in Curved Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

† "The Circular Arch Under Normal Loads", p. 233.

M. Am. Soc. C. E. The author has shown that the cantilever broke when the water rose to the top of the dam; he also has shown that, according to his views, the deflection of the ring 28 ft. above the base was considerably larger than it would be according to the cylinder theory; therefore, nothing less than the water pressure should act at that elevation. Even if by a more judicious selection of the modulus of elasticity, a larger deflection might be calculated by the cylinder theory, the actual deflection is so large that no reputable engineer will dare to be satisfied unless the arch ring is strong enough to sustain the entire water pressure. What, according to the author, happens in such a case? The negative thrust or pull (the author seems to speak of a positive thrust), due to the shortening of the arch, according to his Equation (1*a*), is:

$$H = 0.75\, f'_c\, \frac{t^3}{h^3}$$

Mr. Jorgensen gives*:

$$f_c' = 300 \text{ lb. per sq. in.};$$
$$t = 36 \text{ ft.}; \text{ and}$$
$$h = 28 \text{ ft., approximately.}$$

Therefore,

$$H = 0.75 \times 144 \times 300 \times \frac{36^3}{28^2} = 2\,000\,000 \text{ lb. per lin. ft.}$$

This pull produces at the abutment a moment of

$$2\,000\,000 \times \left(\frac{2}{3} \times 28 \text{ ft.}\right) = 37.3 \times 10^6 \text{ ft-lb.}$$

According to the author, the extreme fiber stresses equal

$$\frac{37.3 \times 10^6}{\frac{36^2}{6}} = \pm\ 172\,000 \text{ lb. per sq. ft.}$$

The pull of 2 000 000 lb. produces, according to Mr. Noetzli's reasoning, a tension of

$$\frac{2\,000\,000}{36} = \ldots\ldots\ldots - 55\,500 \text{ lb. per sq. ft.}$$

or a maximum tension of 227 500 lb. and a compression of 116 500 lb. per sq. ft. To these stresses are to be added the compressive stresses from the pure arch action of $300 \times 144 = 43\,200$ lb. per sq. ft., giving a maximum tension of 184 300 lb. and a maximum compression of 159 700 lb. per sq. ft. Evidently, according to the author's approximate theory, the arch ring cannot carry the load; still, the dam has not shown any sign of failure.

WILLIAM CAIN,† M. AM. SOC. C. E. (by letter).—With regard to the Barren Jack and the Salmon Creek Dams, the author raises the interesting question as to whether they can be regarded as fixed at the base or simply supported there. The bending moment on the supposed vertical cantilever at

* *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), Plate XIII, p. 709.

† Prof. of Math., Univ. of North Carolina, Chapel Hill, N. C.

the crown, 1 ft. thick, the weight of the cantilever being neglected, has not been computed for either dam. It has been computed for the Wooling Dam and, at the base, for full water load, the bending moment* is: $M_w = 220\,900$ ft-lb., and for a fall of temperature of 20° Fahr., $M_t = 127\,700$ ft-lb.

The Wooling Dam is 33 ft. high, vertical on the reservoir side, 2.2 ft. thick at the crest, and 4.4 ft. thick at the base, and will be supposed not to be reinforced. By the usual formula, $M = S\,\frac{I}{c}$, the unit tension on the up-stream side of the cantilever at the base, due to M_w, is 475 lb. per sq. in., and that due to $M_w + M_t$, combined, is 708 lb. per sq. in. The weight of the dam, 16 335 lb., acts vertically; the line of action cutting the base 0.49 ft. up stream from the center, gives a compression of 43 lb. per sq. in. at the up-stream side. Therefore, the total unit stress, due to the bending moments and the weight of the dam, is: Water load and weight of dam, 432 lb. per sq. in.; and water load, fall of temperature of 20° Fahr., and weight of dam, 665 lb. per sq. in.

For either case, plain concrete would crack and the dam could only be regarded as supported at the base with no resisting moment there. At first, when the water is sufficiently low and the temperature is near the mean, the bending moments could be resisted by the base and the cantilever would be fixed at the base, with a vertical generator. Should the water gradually rise, or the temperature gradually fall, a stage would be reached at which the tension on the up-stream side of the cantilever would exceed the limit for concrete in tension (100 to 200 lb. per sq. in.), and the concrete would crack. The cracking would continue as the water rose to the crest and the temperature fell 20° Fahr., and the dam would change from the condition of fixed at the base, to that of simply supported at the base, with no bending moment there and with a generator inclined down stream for reasons to be given later. As the dimensions of the Barren Jack Dam do not differ greatly from those of the Wooling Dam, the conditions at the base are practically the same, or the dam is simply supported at the base.

The solution of the Wooling Dam, not reinforced, regarded as simply supported at the base, with no bending moment there, was given by the writer,† using 7-place logarithms. In the course of the elimination, too few significant figures were left in certain cases to determine accurately the quantities, particularly the deflections at depths from 22 to 29.3 ft. below the crest. On that account, the solution was repeated, using 8-place logarithms with more satisfactory results. The results are recorded in Table 1, in which,

u = radial deflection at the crown; down stream +, up stream —;
T = tangential stress in the horizontal arch; compression +, tension —;
M = moment in vertical cantilever, reckoned as positive when the bending tends to make the generators of the upper cylindrical surface concave to the axis.

The graphs of the quantities u, T, and M, are given in Figs. 6 and 7, the first referring to the water load, the second to the rise in temperature. The vertical

The deflection curve for water load makes an angle with the vertical at the base, the tangent of which is $\frac{0.062}{3.7 \times 12} = 0.001396$, the angle being 4′ 48″.

For the temperature curve, the corresponding angle is 2′ 43″. The influence of the weight of the cantilever has not been included in Table 1. Also, since $M = 0$ at the base, there can be no vertical pressures on the base due either to water pressure or temperature change. The inclinations of the deflection curves to the vertical at the base are evidently due to the difference in the arch thrusts, at and just above the base, corresponding to different deflections. Thus, at the base, $T = 0$, and there is no displacement; whereas, at $d = 29.3$, the compression for water load, $T = 30\,566$ lb. The consequent shortening of the horizontal arch there gives a displacement down stream.

This is the full and complete explanation of the angles in question for the Wooling Dam, and the writer believes that it applies equally to the Barren Jack and Salmon Creek Dams. The case is one of shear (as in the case of torsion), in which each horizontal arch of infinitesimal height, slips over the one just below it.

This reasoning does not explain the "knees" in the deflection lines of the Salmon Creek Dam, since for a homogeneous dam, the deflections should continue to increase to the top (Figs. 6 and 7). The material was evidently not of uniform quality there, and it looks reasonable to suppose a weakening of the cantilever and a possible crack.

Attention may be called to the crossing of the deflection curves of May 25th and August 10th, 1909, of the Barren Jack Dam. Of course, the first curve should lie entirely to the right of the second, as the temperature is lower by 13° Fahr. The explanation appears to be either that the observations were inexact, or that the lower half of the dam did not respond as quickly as the

upper part to the change in air temperature. The reservoir was full on both dates and the change in deflection at the crest was $0.58 - 0.52 = 0.06$ in., or 0.00462 in. per degree.

Compare this with the results for December 24th and December 26th, 1908, when, with the reservoir empty, there was a fall in temperature of 30° Fahr. and a deflection change of 0.052 in., or only 0.0017 in. per degree, less than half the preceding rate. It should have been greater than the preceding rate, for many of the arches were in tension and doubtless cracks were in evidence both in the body of the dam and at the abutments, as there was no reinforcement. Evidently, in the two days, from December 24th to December 26th, the time was not sufficient for the dam to respond to the change in air temperature of 30° Fahr. There was a lag, and this should always be considered for cases of sudden changes of temperature.

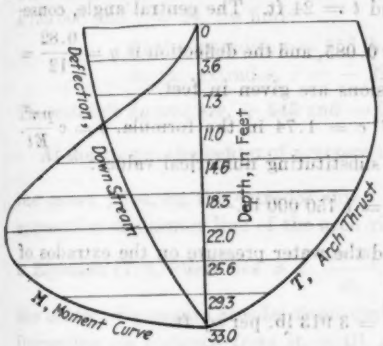

FIG. 6.

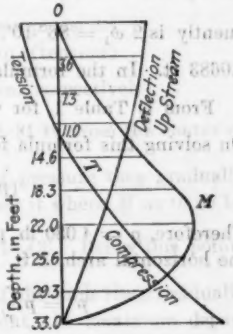

FIG. 7.

In fact, there will always be a lag, even with slow changes in air temperature; and, during such periods, observations of the air thermometer should be recorded daily in order to make a reasonable estimate of dam temperature at a certain date; otherwise, the observations may prove worthless for computing stresses from deflections. For the Barren Jack Dam it is evident that the observations are not full and precise enough to give confidence in the results of computations of stresses for temperature changes only. For thick dams, the subject is further complicated in that the temperatures in the body of the dam vary considerably for the same date, although the analysis, leading to definite formulas, has been based on a constant temperature for the whole body of the dam at a given date. Then, again, in all cases, the uncertainty as to the modulus of elasticity of the concrete in the dam, suggests caution in stating final results.

In the derivation of Equations (1) to (9), the author substituted a parabolic arch for the circular one, replaced the arc length by the span length, and, for the abutment, used the crown thrust for the tangential component. Such approximations may lead to practical results for central angles from about 0 to 30°, for thin arches; but for larger central angles, up to 180°, particularly for thick arches, the results may be greatly in error.

The writer has developed a nearly exact theory of "The Circular Arch under Normal Loads"*, which omits only the influence of shear on deformation, which paper, for brevity, will hereafter be referred to as C, with the formula or table referred to added. The notation given in that paper will be used throughout. A comparison of numerical results, for the same arch, by the use of the writer's formulas and tables and the author's computations, should prove instructive. To that end, consider the observations on the Salmon Creek Dam of October 8th, 1914, and October 27th, 1915. Since the temperatures are not given, they necessarily will have to be assumed to be the same. The deflection at Elevation 1 115, or 108 ft. above the base, on October 8th, 1914, was zero, and on October 27th, 1915, with the water reaching the crest, it was 0.82 in., which will be attributed entirely to the water load. Mr. Noetzli gives the following data: $E = 2\,500\,000 \times 144 = 360\,000\,000$ lb. per sq. ft.; $r = 282$ ft., $h = 76$ ft., and $t = 24$ ft. The central angle, consequently is $2\,\phi_1 = 86° 10'$. Here, $\frac{t}{r} = 0.085$, and the deflection is $\eta = \frac{0.82}{12} = 0.0683$ ft. In the formulas, all dimensions are given in feet.

From C Table 1, for "fixed ends," $c = 1.74$ in the formula, $\eta = c\,\frac{p\,r^3}{E\,t}$. On solving this formula for $(p\,r)$ and substituting numerical values:

$$(p\,r) = \frac{\eta}{c}\,\frac{E\,t}{r} = 1\,150\,000 \text{ lb.}$$

Therefore, $p = 4\,080$ lb. per sq. ft., and the water pressure on the extrados of the horizontal arch, 1 ft. in depth, is:

$$p' = p\,\frac{r}{r'} = 4\,080\,\frac{282}{294} = 3\,913 \text{ lb. per sq. ft.}$$

The moment at the crown of the horizontal arch, at Elevation 1115, is given by the formula,

$$M_0 = -\,a\,\frac{E\,t^3}{r\,h}\,\eta.\dagger$$

The coefficient, a, was computed, but the result, $a = 0.152$, was found to be the same as that obtained from C Table 3. Substituting numerical values,

$$M_0 = -\,2\,435\,000 \text{ ft-lb.}$$

corresponding to compression at the extrados and tension at the intrados.

The thrust, P_0, at the crown is to be derived by aid of C Equation (12),

$$(p\,r - P_0) = \frac{-\,M_0}{r\left(1 - \frac{\sin\phi_1}{\phi_1}\right)} = \frac{2\,435\,000}{282 \times 0.0916} = 94\,400$$

Therefore,

$$P_0 = (p\,r) - 94\,400 = 1\,055\,600 \text{ lb.}$$

By the well known formula:

$$s = \left(\frac{P}{t} \pm \frac{6\,M}{t^2}\right) \div 144,$$

* See p. 233.

† η is to be taken positive down stream, negative up stream.

the unit stresses, in pounds per square inch, at the crown, where $P = P_0$, $M = M_0$, are found to be:

At the extrados, $s = 468$ lb. per sq. in. (compression)
At the intrados, $s = 126$ lb. per sq. in. (compression)

Mr. Noetzli's figures are 461 and 91 lb. per sq. in., respectively.

At the abutment of this horizontal circular arch (of 1 ft. depth), the tangential component of the thrust, P_1, and the moment, M_1, must be computed from C Equation (4) and C Equation (3), or C Equation (13).

$$P_1 = (p\,r) - (p\,r - P_0)\cos\phi_1 = 1\,081\,000 \text{ lb.}$$
$$M_1 = M_0 + (p\,r - P_0)\,h = + 4\,739\,000 \text{ ft-lb.}$$

Therefore, by the formula for s, putting $P = P_1 = 1\,081\,000$, $M = M_1 = 4\,739\,000$ and $t = 24$, we find:

At the intrados, $s = 656$ lb. per sq. in. (compression)
At the extrados, $s = -22$ lb. per sq. in. (tension)

The author's figures are, + 645 and — 89 lb. per sq. in., respectively.

At the crown, the center of pressure is $\frac{M_0}{P_0} = -2.31$ ft. from the center of the crown joint, on the extrados side. The center of pressure then gradually approaches the center line of the arch ring, and crosses it where $M = 0$, or by C Equation (13), where $\cos\phi = \frac{\sin\phi_1}{\phi_1}$, or at $\phi = 24° 43'$. Below this point, the center of pressure recedes from the center line of the arch ring, gradually increasing its distance from it, until, at the abutment, the maximum departure from it, $\frac{M_1}{P_1} = +4.39$ ft., is reached, on the intrados side.

The author gives, on page 300, the dimensions for the highest arch of the Salmon Creek Dam. The deflection is 0.98 in. for a full reservoir. Following the previous method, we find,

$$(p\,r) = 287\,200 \text{ lb.}$$
$$p = 884 \text{ lb. per sq. ft.}; \; p' = 850 \text{ lb. per sq. ft.}$$
$$M_0 = -18\,000 \text{ ft-lb.}; \; P_0 = 287\,000 \text{ lb.}$$

At the extrados, $s = 353$ lb. per sq. in. (compression)
At the intrados, $s = 311$ lb. per sq. in. (compression)

The author does not attempt to estimate the part of the water load carried by this arch; therefore, no final figures are given.

These solutions by the writer are complete, since they include the effects of both bending moment and axial stress, so that nothing has to be added for axial stress due to water load.

When the observed deflection of an arched dam, at any point, is due partly to water load and partly to temperature change, the solution is more difficult. It will be found that the value of $(p\,r)$ can be determined accurately, but that the moments and stresses can be ascertained only approximately. The solu-

tion is based on the reasoning given by the writer in a previous discussion*, leading to the formula for deflection, D,

$$D = \frac{3}{2}\frac{r'\,T}{E\,t} - e\,r'\,t_0,$$

in which the Smith formula for deflection, due to T, is given, in order, presently, to compare numerical results.

In this case,

T = tangential stress, for width, t, at crown of horizontal arch of depth 1 ft., due both to water load and temperature change. When in compression, it is positive; when in tension, it is negative.

r' = radius of extrados (= 135 ft. for Wooling Dam).

e = coefficient of expansion for change of temperature of 1° Fahr. = 0.000 0055 (Smith).

t_0 = number of degrees Fahrenheit of change in temperature above or below an assumed mean. For rise of temperature, t_0 is positive; for a fall, it is negative.

If the tangential stress due to water load, is denominated as T_w, and that due to change of temperature, T_0, then T_w is always positive, but T_0 can be positive or negative. Also, since t_0 can be positive or negative, there are four cases, all of which were carefully provided for in the foregoing formula. Careful attention must be given to the algebraic signs. When D is positive, it indicates a radial deflection down stream.

As Smith gives the modulus for the horizontal arch,

$$E = 2\,000\,000 \times 144 \text{ lb. per sq. ft.},$$

it will be used in this formula. For a rise of temperature of 20° Fahr., on substituting numerical values and multiplying by 12 to reduce to inches,

$$D = 0.000\,00844\,\frac{T}{t} - 0.178$$

in which D is in inches. For a fall in temperature of 20° Fahr., change the sign of 0.178. T and t have the same values as before, t being in feet, and T in pounds.

In Table 2, Columns 5 and 8 are computed by the foregoing formulas. The other columns are filled out from Table 1 for the Wooling Dam, not fixed at the base. For t_0 positive, the quantities for water load and temperature are algebraically added. Thus, the total deflection and thrust are due to both causes. For t_0 negative, change the signs of u and T, under "Temperature changes", and add algebraically to the values of u and T, respectively, in the second and third columns of Table 1.

As the third decimal figure in the values of u in Table 1 cannot be relied on, the results for deflections (Columns 3 and 5 or Columns 6 and 8) compare very well. Similar results follow from use of the quantities pertaining to the dam fixed at the base. This should tend to give confidence in the formula for D and its applications.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), pp. 79–87.

A more accurate formula for D will now be written, by replacing the first term for deflection, due to T, by $c \frac{p r^2}{E t}$, and the last term by, $e r t_0$,

$$D = c \frac{p r^2}{E t} + e r t_0$$

in which D is in feet, and, as before, r is the radius of the center line of an arch, on which the normal unit pressure, due to the combined water load and temperature change, p, is positive when directed toward the center; otherwise, it is negative. For a given central angle and a value of $\frac{t}{r}$, the value of c is to be taken from C Table 1.

TABLE 2.

		Water Load and 20° Fahr. Rise of Temperature.			Water Load and 20° Fahr. Fall of Temperature.		
d, in feet.	t, in feet.	Total deflection, in inches.	Total thrust, T, in pounds.	D, in inches.	Total deflection, in inches.	Total thrust, T, in pounds.	D, in inches.
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
0	2.2	+ 0.092	+ 71 430	+ 0.087	+ 0.692	+ 117 770	+ 0.630
18.3	3.42	+ 0.085	+ 107 190	+ 0.096	+ 0.357	+ 72 210	+ 0.356

On solving for $(p r)$, we find,

$$(p r) = \frac{E t}{c r} (D + e r t_0),$$

all dimensions being in feet. For a water load and rise of temperature, t_0 is positive; for a water load and fall of temperature, t_0 is negative.

Some of the results for the Barren Jack Dam will now be examined. On December 24th, 1908, with reservoir empty, the temperature was 87° Fahr.; and the deflection was zero. On August 10th, 1909, with reservoir full, the temperature was 60° Fahr., and the deflection, at a point 17 ft. above the base, was 0.36 in. In this case, there was a fall in temperature of 27° Fahr., thus

$$D = \frac{0.36}{12} = 0.03 \text{ ft.}$$

$$t_0 = -27$$

At the point 17 ft. above the base, the author gives: $r = 78$ ft., $h = 10$ ft., $t = 4$ ft.; whence, $2\phi_1 = 58° 40'$, $\frac{t}{r} = 0.0513$, and, therefore (C Table 1), $c = 1.65$, for an arch with "fixed ends".

Let $E = 2\,500\,000 \times 144 = 360\,000\,000$ lb. per sq. ft.; $e = 0.0000055$; therefore, $r\ e\ t_0 = -0.01158$, and $(D + e\ r\ t_0) = 0.01842$. Substituting numerical values in the formula,

$$(p r) = 206\,100 \text{ lb.}$$

The deflections under the water load and a fall of temperature are both down stream, giving compression at the extrados, tension at the intrados, from bending moment at the crown, which is negative.

From C Table 3,

$$a = 0.160 \text{ for water load;}$$
$$a = 0.170 \text{ for temperature.}$$

Let,

$$\eta_w = \text{deflection from water load,}$$
$$\eta_0 = \text{deflection from fall of temperature.}$$

Both these are unknown, but the following relation is true:

$$\eta_w + \eta_0 = D.$$

The total moment at the crown from both deflections, can be written:

$$M_0 = -\frac{E\,t^3}{r\,h}\,[0.160\,\eta_w + 0.170\,\eta_0]$$

An assumption will have to be made as to the values of η_w and η_0, expressed in terms of D, in order to effect a solution. Fortunately, the Barren Jack Dam and the Wooling Dam have nearly the same dimensions, and by reference to Table 1, it may be inferred that the deflections for the Wooling Dam, from water load and a fall of temperature, of 27° Fahr., are nearly the same; so that it will be assumed that the same relation holds for the Barren Jack Dam. Assume that, $\eta_w = \eta_0 = 0.5\,D$, therefore,

$$[0.160\,\eta_w + 0.170\,\eta_0] = \frac{1}{2}\,[0.160 + 0.170]\,D = 0.165\,D.*$$

On substituting numerical values,

$$M_0 = -\frac{360\,000\,000 \times 64 \times 0.165 \times 0.03}{78 \times 10} = -146\,200 \text{ ft-lb.,}$$

$$\therefore p\,r - P_0 = \frac{-M_0}{r\left(1 - \dfrac{\sin \phi_1}{\phi_1}\right)} = \frac{146\,200}{3.354} = 40\,600 \text{ lb.}$$

$$\therefore P_0 = p\,r - 40\,600 = 165\,500 \text{ lb.,}$$

and the unit stresses at the crown are,

$$s = \frac{1}{144}\left[\frac{165\,500}{4} \pm \frac{6 \times 146\,200}{16}\right]$$

$$= \begin{cases} + 668 \text{ lb. per sq. in. (compression) at the extrados;} \\ - 93 \text{ lb. per sq. in. (tension) at the intrados.} \end{cases}$$

The author derives,

$$\begin{cases} + 495 \text{ lb. per sq. in. (compression) at the extrados;} \\ - 242 \text{ lb. per sq. in. (tension) at the intrados.} \end{cases}$$

As another illustration of the decided influence of temperature change compare the deflection lines, Fig. 1, for December 24th, 1908, and for May 25th, 1909, at a point 17 ft. above the base. The fall of temperature is $87 - 47 = 40°$ Fahr.; and the deflection is, 0.32 in. Therefore, $t_0 = -40$, and $D = \dfrac{0.32}{12} = 0.0267$ ft. Following exactly the method used in the last

*If, for a much greater fall of temperature, it was estimated that $\eta_w = 0.4\,D$; then, since, $\eta_w + \eta_0 = D$, it follows that $\eta_0 = 0.6\,D$, and $(0.160 \times 0.4 + 0.170 \times 0.6)\,D = 0.166\,D$. This illustrates the method to be followed in any case.

example, writing $(0.160\ \eta_w + 0.170\ \eta_0) = 0.167\ D$, the unit stresses are found to be, at the crown,

$$\begin{cases} + 460 \text{ lb. per sq. in. (compression) at the extrados;} \\ - 226 \text{ lb. per sq. in. (tension) at the intrados.} \end{cases}$$

In this case, the thrust and bending moment at the crown are $P_0 = 67\,300$ lb. and $M_0 = -131\,600$, respectively. The great decrease in the thrust and a smaller (numerical) decrease in the bending moment, as compared with previous values, accounts for the great differences in unit stresses. Note that the unit tension at the intrados (226 lb. per sq. in.) is much larger than the value (93 lb. per sq. in.), as computed for the preceding case.

The horizontal arch considered, was taken as "fixed at the ends", in order to compare the results with those of the author. As this arch was only 4 ft. thick, and not tied at the ends with reinforcement, it is doubtless intermediate between an arch "fixed" and hinged at the ends; so that, properly, the solution should be made for both cases, and intermediate values for the unit stresses written, depending on the conditions at the ends as constructed.

As to the confidence to be placed in results, it may be noted that the theory for water load alone is exact, but the theory of the influence of temperature changes is approximate. As first outlined by B. A. Smith, M. Am. Soc. C. E.,* the latter theory is open to some objections; but as it is the best that has been proposed, this theory was adopted; particularly as it was believed that it gave close approximations to temperature stresses in arched dams. There is another matter of importance which affects the accuracy of computed stresses from observed deflections, namely, the influence of vertical cracks in the masonry. Such cracks must close before arch action takes place, and there is a deflection during this closing when cantilever action alone is exerted. The total observed deflection is made up of the part due to the closing of the cracks and the part corresponding to the dam exerting both full arch and cantilever action. The formulas do not take account of the deflection due to closing of the cracks, and not completely of the subsequent deflection, since the dam is under action as a cantilever at the beginning of this later deflection. If the total deflection is used in the formulas, the dam is assumed to be without cracks at any stage. If it was possible to observe the deflection and temperature at the time of closing of any cracks, then the subsequent deflection can be regarded as the value of D in the formula, but t_0 must be taken as the difference between the temperatures (with the proper sign) at the time of closing of the cracks and the time of the final observation when the deflection is greatest. If the total deflection, including that corresponding to the closing of the vertical cracks, is taken as the value of η in the formula,

$$(p\,r) = \frac{\eta}{c}\frac{E\,t}{r}$$

the value of $(p\,r)$ will always be too great. In fact, for quite large cracks, it is easy to conceive of the deflection due to the closing of the cracks being the greater part of the total deflection, so that $(p\,r)$, as computed, should have more than double its true value. Of course, if $(p\,r)$, as computed, should prove

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 2027.

to be greater than its value for full water pressure at the base of the dam, the absurd result would show at once, either the influence of wide cracks or inexact observations.

It is thus seen that the author's analysis, in addition to the approximations introduced by substituting a flat parabolic arc for the circular arc, suffers from the lack of a precise method for estimating the part of the water load sustained by the arch. At the crest of the dam, it is never attempted. However, it is easy to supply this omission, since $(p\,r)$ can be readily computed, as already shown, either by the use of the author's formula for deflection or by the writer's more precise formulas for either fixed or hinged ends.

The arch thrust due to rib-shortening alone is given in a precise manner by the author's Equation (14), in connection with Fig. 4. Similarly, the author's Equation (18), in connection with Fig. 5, gives a precise estimate of the thrust due to temperature changes. Many of the results of C Table 2, expressed in terms of $\frac{t}{h}$, were compared with those of the author for temperature thrust and found to agree very well, thus affording a mutual check. It must be borne in mind that such values of H_t pertain to a free arch and do not include the influence of the reactions of the cantilevers. Both influences must be included to find the thrust for the arch regarded as a part of the dam.

In conclusion, it may be stated that the author has done good service in calling attention to the importance of a proper interpretation of the observations of deflections of curved dams. Such observations should be made with extreme care, or they may be misleading, remembering that minute changes in deflection correspond to appreciable changes in stresses. Further, daily observations of the temperature of the air should be recorded, and the times for observations of deflections should be at periods when there is not much change in temperature.

B. F. Jakobsen,* Assoc. M. Am. Soc. C. E. (by letter).—Referring to the discussion of the deflection curve of the Salmon Creek Dam, the author states:

"A cantilever fixed at the base * * * would have the line of zero deflection as a tangent, approximately as shown by a typical cantilever deflection curve in Fig. 2."

As the writer showed† in discussing the author's paper, "Gravity and Arch Action in Curved Dams," the deflection curve of a dam like the Salmon Creek Dam is not vertical at the base, but makes a considerable angle with the vertical due to the shear deformation. The author's statement is approximately true for ordinary beams, in which the length of the beam is considerable compared with its height; when the length of the beam is considerably less than its height, the deflection due to shear exceeds the deflection due to bending, as shown in Table 15 and Fig. 32, of the writer's discussion referred to.

* Designing Engr., San Joaquin Light and Power Corporation, Fresno, Calif.

† *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 99.

The angle, α, at the base of the Salmon Creek Dam, on the assumption that the dam acts as a cantilever, is found from the writer's Equation (45)*:

$$t g \alpha = \frac{d y_h}{d x} = \frac{1.2 S_h}{144 G b}$$

in which $S_h = 31.3$; $h^2 = 31.3 (H - x)^2$ lb. for 1 ft. width of dam; G is the coefficient of rigidity $= \frac{E}{2.4} = 1\,040\,000$ lb. per sq. in., b = the base = 42 ft. and $H = 160$ ft.†

This gives $\alpha = 0° 0' 33''$, at the base. The typical cantilever deflection curve, as shown by the author in Fig. 2, is given in the correct shape in Fig. 32 of the writer's discussion to which reference has been made.

The lower 28 ft. of the dam may be considered as a rectangular section, the base being 42 ft. and the height 28 ft., as shown in Fig. 3. The top of this 28-ft. section has moved down stream $\frac{3}{8}$ in., and this is accounted for by the author by cracks which he claims have been produced in the up-stream face of the concrete and close to bed-rock. He then says:

"Such cracks, of course, will extend only for a comparatively short distance into the dam body, and the water-tightness is insured sufficiently by the increased compression stresses near the down-stream side."

If the dam has developed cracks in a horizontal plane near the base, then the total deformation of the concrete is practically negligible and that means that the crack in the up-stream face must be:

$$0.375 \times \frac{42}{28} = 0.56 \text{ in.}$$

If this crack exists it must extend practically through the dam, and seepage would most likely take place at this point. The probability would be in favor of one large crack instead of several small cracks.

To account for the $\frac{3}{8}$-in. movement 28 ft. above the base of the dam, the author calculates that a uniformly distributed load of 20 000 000 lb. would be required, and, in doing so, entirely neglects the shear deformation. The shear diagram is a triangle 28 ft. high with 25 400 000 lb.‡ as a base and, therefore,

$$S_h = 25\,400\,000 \frac{H - x}{H}$$

and the deflection due to shear alone is,

$$y'_h = \int_{x=0}^{x=28} \frac{12 \times 1.2}{144 G \times b} \times S_h \, d x = 0.815 \text{ in.}$$

The total deflection due to shear and bending is, therefore, 1.19 in., or 3.17 times as great as the deflection calculated by the author. The load distribu-

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 99.

† *Loc. cit.*, Fig. 31, p. 99.

‡ Using $E = 2\,500\,000$, as the author does, the writer obtains 25 400 000 lb. instead of the author's 20 000 000 lb. and a tension of 8 400 lb. per sq. in., instead of the author's 6 600 lb. per sq. in.

tion assumed by Mr. Noetzli seems very improbable. The more proper load distribution would be to assume a shearing force as a maximum 28 ft. from the base and as zero at the base, so that,

$$S_h = 25\,400\,000\,\frac{x}{H}$$

This gives a deflection 6.34 times as great as that computed by Mr. Noetzli and, therefore, a maximum stress of 1 325 lb. per sq. in. instead of the author's 8 400 lb. per sq. in. This is on the assumption that the base is fixed, which, in the writer's opinion, is untenable.

The author has evidently overlooked the most interesting point on the deflection curve, that is, the knee at Elevation 1075 (Fig. 2). This point is deflected 0.625 in., while the point at Elevation 1095 is deflected only 0.540 in., or 0.085 in. less. If the fact that the dam below Elevation 1075 is not vertical is taken into account, the relative deflection is 0.185 in. in the 20 ft. of dam. The average thickness of the dam at this place is approximately 31 ft., so that if this deflection is due to bending with a uniform load, as the author assumes, there must exist in the down-stream face, at Elevation 1075, a vertical tensile stress of:

$$s = \frac{2\,E\,h}{L^2}\,y = 5\,950 \text{ lb. per sq. in.}$$

in which,

$E = 2\,500\,000$ lb. per sq. in.;
$h = 31 \times 12$ in.;
$L = 240$ in.; and
$y = 0.185$ in.

If it is assumed, as seems more logical, that the beam is 40 ft. long, fixed at the ends, and uniformly loaded, and that the deflection in the middle is 0.085 in., then,

$$s = \frac{16\,E\,h}{2\,L^2}\,y = 2\,750 \text{ lb. per sq. in.}$$

There should be, therefore, according to the author's theory, a horizontal crack in the down-stream face at Elevation 1075. As no crack has been reported, the writer assumes that none exists.

The fact that no horizontal crack has developed in the down-stream face at Elevation 1075 affords an excellent example of the large deformation a concrete dam can undergo, without producing cracks, and in spite of the fact that a tension of about 2 750 lb. per sq. in. should exist at that point according to the ordinary formula for bending. It shows that the ordinary bending formulas are entirely inapplicable.

In view of the fact that no cracks have developed in the visible down-stream face, there is no reason to expect any cracks in the up-stream face. It is very fortunate that Mr. Noetzli has applied his theory to the Salmon Creek Dam, as this affords a means of checking his analysis against known facts and shows that his assumptions of cracks in the up-stream face are not verified.

Regarding the accuracy of the deflection measurements, L. R. Jorgensen, M. Am. Soc. C. E.,* mentions the great difficulty of measuring such deflections accurately near the base of the dam, and any one familiar with such measurements will not fail to realize this.

The aim of the author, to determine stresses from deflections, is far too ambitious an undertaking with the present state of knowledge. The method may yield valuable and approximate information in the hands of one who fully understands the limitations imposed by the assumptions. In unskillful hands, the method is bound to lead to conclusions which cannot be substantiated and which are likely to be incorrect.

In the interest of scientific precision, the writer would suggest that phrases such as that used by the author, for example:

"A further proof that this dam has developed horizontal cracks at the up-stream side is shown by the following calculations: * * *"

should not be used, unless the dam is known to have cracked. As expressed by the author, it may be misleading.

In summing up, the writer can do no better in expressing his opinion than by quoting from the discussion, by D. C. Henny, M. Am. Soc. C. E., of the author's paper, "Gravity and Arch Action in Curved Dams":†

"The reason that the mathematical treatment by the author carries no conviction is that, owing to the complexity of the problem, it is extremely incomplete and ignores numerous important elements to which he himself, * * *, makes able reference."

CHARLES P. DUNN,‡ ASSOC. M. AM. SOC. C. E. (by letter).—An appreciation of Mr. Noetzli's enthusiasm and his able efforts to solve a difficult problem, prompts the writer to add to the discussion, in the hope of being helpful.

The large amount of capital to be spent in projected water-control works in the near future makes it desirable that the study of arch dams should be continued, in order that engineers may accept improved methods of design as soon as possible. Even a slightly better understanding of the subject will save many thousands of dollars.

On account of the shrinkage of concrete on setting, and the variations of volume with temperature, it appears to be practically impossible to design an unreinforced arch dam in which the cantilever stresses will not be excessive (at least from a theoretical standpoint), unless the deflection allowed by shrinkage is largely eliminated by grouting the cracks and construction joints or by closing narrow vertical openings in the dam when the temperature is slightly below the mean after shrinkage in the main body of concrete has taken place.

The writer favors the latter method because, as Mr. Noetzli has pointed out, if the grouting is poorly done, the dam is injured by an uneven distribution of compressive stresses and the introduction of bending moments in the arches. It has also been pointed out that it is impossible to know positively to what extent a joint or crack has been filled with grout, and attention has been

* *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 319.
† *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 121.
‡ Designing Engr., Skagit River Power, Seattle, Wash.

called to the difficulty and uncertainty of building up a high grouting pressure, due to the friction head of grout flowing in small cracks, and to the difficulty of forcing the crest up stream, due to the leakage of grout from the last seam to be filled when sufficient pressure is applied to move the crest.

No agreement has been reached on the amount and importance of rock deformation under and at the abutments of the dam. These deformations are classed by different engineers from infinitesimal and negligible to appreciable and of consequence. It appears that unless deflection measurements are complete, covering practically the entire surface of the dam, an unknown rock deformation would introduce error into the determination of stresses from deflections.

If complete analysis of stresses is to be made from deflection measurements, the existence or non-existence of cracks must be ascertained, and existing cracks must be located.

Engineers do not agree as to what extent the uncertain element of the "flow" of concrete or the change of the modulus of elasticity with time may enter into the determination of stresses from deflection measurements.

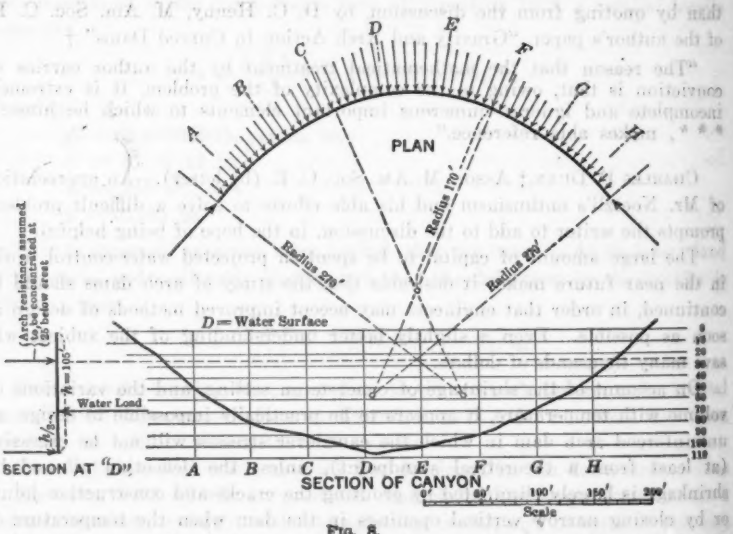

FIG. 8.

Mr. Noetzli has already shown* that in the ordinary type of arch dam the upper horizontal arches carry a greater load than is imposed on them directly by water pressure, the additional load being transferred to the upper zone by vertical beam action. He has worked out a method for determining approximately the distribution of load between the vertical beams and the arches by considering that the beams are supported throughout their length by arches of varying stiffness or ability to carry load. The writer is confused by the thought that,

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

in addition to the foregoing assumption, it seems necessary to consider also that the arches are supported throughout their length by cantilevers of varying stiffness and that load may be transmitted horizontally from a region of flexible cantilevers to a region of stiff cantilevers by a portion of the arch acting as a beam. In other words, if the cracks are closed and the dam is acting as a whole, the deflection of any single point in the dam changes the stress in every horizontal arch and every vertical beam in the dam, which condition throws doubt on the applicability of the comparatively simple formula used by Mr. Noetzli to obtain the arch deflection. It seems that the use of this formula might introduce an error of some magnitude into the calculations for a dam built at an irregular site. In his evidently thorough study of the problem, Mr. Noetzli has no doubt covered this point.

It appears to the writer that, in general, the arches in the usual type of dam have not a uniform normal load, for the following reasons:

1.—The upper arches are loaded by (*a*) a uniform normal load imposed directly by the water pressure, plus (*b*) an additional load imposed by the vertical beams, which additional load is greater near the crown than near the abutments. Mr. Noetzli's calculations show that a certain additional load (*b*) exists. This additional load will probably be greater in quantity than his calculations show, because of rock deformation and because of hydrostatic pressure under the dam. The effect of these uncertain deformations and forces will be to increase the condition of uneven loading of the arches.

2.—Take a zone near the middle of the height of the dam. The arches may carry a certain part of the load near the crown, which loading diminishes to zero as one goes along a horizontal plane to the side of the canyon, at which point all the load is carried by the cantilevers.

To illustrate this point an approximate calculation has been made of a hypothetical dam which is assumed to have no resistance as a cantilever, the water load being carried by vertical beams supported at the base by the foundation and near the top by an arch in a horizontal plane, all the resistance by arch action being assumed to be concentrated at one elevation. The site is the usual U-shaped canyon, as shown in Fig. 8. With this extreme assumption, the uneven loading of the horizontal arch gives a linear arch of maximum curvature at the deepest part of the canyon, the curvature decreasing to almost a straight line at the abutments. The three circular arcs occupy closely the position of the somewhat irregular linear arch.

The true condition in an actual dam must be such that the center line of pressure resulting from the loading of the horizontal arch slices will be somewhere between a circle and the hypothetical extreme shown in Fig. 8.

It appears to the writer that a deviation from the exact circular form, following as closely as practicable the true line of pressure of the elastic arch as determined by studies of existing structures, will effect an economy of material because of reduction of bending moments in the horizontal arches, without necessarily increasing the unit stresses now considered proper.

Such a deviation from the circular form concentrates a larger portion of the total curvature in the deeper part of the canyon, and, at a few sites, might make

it economically advisable to substitute conical surfaces for the warped surfaces of the constant-angle arch.

A test of miniature dams covering this point would be extremely interesting and would probably develop some worth while data.

ALBERT B. HILL,* M. AM. SOC. C. E. (by letter).—The author has raised some interesting questions which merit discussion.

If the deflections of the dam have been carefully measured and the character of the forces that produced the deflections, together with the elastic modulus of the material, are definitely known, the stresses resulting from the deflections should be determinable. There can be no serious question on that point.

In referring to "Stresses in the Vertical Cantilevers of Arch Dams", the author bases his method of determining those stresses on the "well known theory of stresses and corresponding deflections in cantilever beams". The usual formulas for cantilever beams are deduced from the theory of flexure, assuming the beams to be rigidly fixed at the base, with compression on one side of the neutral axis and tension on the other side. The writer questions whether formulas are strictly applicable to dams generally, which may not be rigidly fixed at the base.

The author assumed the dam to be "rigidly fixed at the base due either to its own weight or to special anchorage to the bed-rock". The value of the weight, as a fixing force, is limited to the condition of the dam as simply supported at the base. When the load commences to produce tension in the up-stream face of the dam near the base, the weight of the dam as a fixing force is exhausted. An adequate anchorage for rigidly fixing the base is required, if the formulas for rigidly fixed cantilevers are to apply. The absolute adequacy of such anchorage for rigidly fixing the base permanently, may be uncertain.

In his investigations of the Barren Jack Dam in Australia and the Salmon Creek Dam in Alaska, the author finds that the deflection curves, instead of being tangent to the normal at the base, make material angles with the normal at their intersection with the base. Such a condition indicates clearly, that whatever the intentions of the designers may have been, the dams are not rigidly fixed at the base, and renders questionable the application of formulas for a rigidly fixed base. If the dams are simply supported at the base, the deflections would be greater than if they are considered as rigidly fixed at the base. This may help to account for some of the great differences between the measured deflections and the calculated deflections of the author.

The writer doubts the wisdom of using steel reinforcement for anchoring and for resisting tension in high concrete dams subject to heavy water pressure. It is imperative that important impounding reservoirs should be designed as permanent structures. The dangers to life and property and the loss that would be caused by a failure renders inadmissible the construction of any but permanent dams. The steel reinforcement to be most efficient should be reasonably near the up-stream face of the dam. The farther it is removed from the up-stream face, the more steel is required. The amount required is

* Cons. Engr., New Haven, Conn.

large in any case if the up-stream face of the dam is to be "rigidly fixed" at the base.

Concrete, if of good quality and under only light water pressure, may protect the steel fairly well. Concrete, however, is more or less porous and water, under heavy pressure, will be forced through a few inches or even a few feet of it. If the unit stresses are equal to those generally allowed in steel reinforcement, then, in accordance with the laws of elasticity, the steel will stretch somewhat. This will produce tension in the concrete, tending to open fine hair cracks and make it still more porous.

Water under high pressure is also likely to get to the steel through contraction joints and through construction joints where weak laitance may not have been entirely removed. Damp spots, where water has seeped through, are not infrequently noticed on the down-stream face near the bottom of dams of only moderate height, particularly soon after the dams are put in commission.

If water does get to the steel and corrosion takes place, the concrete is likely to be split and trouble will result where it may not be seen. Corrosion of the steel has already caused trouble in reinforced concrete stand-pipes built less than a score of years ago. The writer believes it is safer to omit the steel and use a little more concrete, and consider the dam as simply supported at the base, unless the steel is much more efficiently protected than in present practice.

A force which is helpful to the arched dam, and which seems to have been given little, if any, attention, is simple vertical beam action. Vertical slices of the dam may be considered as simple vertical beams, supported at the base in the rock and, to a limited extent, supported at the top by horizontal arch action. In considering arch action, the dam is assumed to be divided into horizontal slices free to slide on each other. On this assumption, the horizontal arch slices at the top, theoretically, are not stressed from water pressure, as they are above the water level. These top horizontal arches should be made to do useful work, which they actually do, by acting as limited supports to the top of the simple vertical beams.

The writer believes that the top of an arch dam should be of substantially the same thickness as the top of a corresponding gravity section dam. The rigidity of a simple beam varies as the cube of the depth. If an arch dam is, say, 12 ft. thick at the top and 60 ft. thick at the base, the thickness at the base being five times the thickness of the top, the rigidity near the base would be about one hundred and twenty-five times the rigidity near the top. The maximum water pressure is also at the bottom. Therefore, the simple vertical beam, with relatively small support at the top, is able by its rigid bottom portion, to transmit a material part of the bottom water pressure, into the rock foundation.

The simple vertical beam action would tend to produce tension in the down-stream face of the dam, thereby neutralizing a portion of the compression in the down-stream face resulting from simple gravity action. It would also tend to produce compression in the up-stream face of the dam, helping to neutralize any tension in the up-stream face resulting from gravity action, or

cantilever action, in a reduced gravity section. The simple vertical beam action is relatively about four times more efficient than cantilever action. Such action therefore would be helpful to gravity action and permit more load to be put on gravity action without producing tension in the up-stream face of the dam. It also helps in distributing the water pressure over the horizontal arch slices, tending to make the unit stresses in the arches more nearly uniform, as well as helping to transmit some water pressure quite directly into the rock bottom.

The various forces acting in arch dams make them, as the author has stated, "statically complicated structures", and he evidently appreciates the difficulties of an exact mathematical solution by a general formula that would be of practical value.

In the thicker bottom portions of the arch dam, shearing stresses—mostly horizontal and inclined, but some vertical—are a material factor in transferring the loads into the rock. The concrete near the bottom is so massive that the unit stresses in shear are relatively small, even for transmitting the greater part of the bottom water pressure. The principal resisting forces acting in arch dams are shear—horizontal, vertical, and inclined; simple gravity action; horizontal and inclined arch action; simple vertical beam action; some horizontal beam action; and cantilever action. On the principle of least work, all these different forces do work in proportion to their relative efficiencies or rigidities. With all these resisting forces marshaled, one may perhaps cease to wonder that arch dams have not failed.

Considering the dam as simply supported at the base, the deflection due to gravity action can be determined with a close degree of approximation, starting from the resultant pressure curve constructed by considering the weight of the masonry, the water pressure, and a reasonable allowance for uplift. The proper allowance for uplift depends on the character of the foundation. Some engineers (although probably few) advise allowance for uplift equal to the full static head on the base of the dam, or, in other words, that the dam is floating on water, which is impossible. Other engineers advise an allowance for uplift equal to the full static head at the up-stream edge, decreasing to zero at the down-stream toe of the dam. This is more reasonable; but the writer is of the opinion that it is more than necessary in many cases.

Where the foundation is sound, solid rock, where dense concrete is used, and a thick layer of soft mortar is spread over the surface of the rock before the concrete is placed, an allowance for uplift equal to half the static head at the up-stream edge of the dam, decreasing to zero at the toe, or, better, to the ground-water level at the toe, if the ground-water level is above the toe of the dam, will prove sufficient for full gravity section dams.

In arch dams, horizontal arch action and vertical uplift act at right angles to each other. Therefore, theoretically, uplift does not directly affect horizontal arch action. Practically, however, uplift diminishes the efficiency of gravity action and thereby throws more work on arch action. Owing to the probability of a little tension in the up-stream face of arch dams before much arch action

becomes effective, allowance for uplift in arch dams should be fully as much as for full gravity sections. The engineer must use his judgment as to how much allowance should be made for uplift in any special case.

The writer believes that in the allowance for ice pressure there has been a tendency sometimes to over-estimate its importance. It is a well known principle of physics that pressure produces heat, and the melting of ice by pressure applied on it is one of the familiar demonstrations of the principle. If through a rise in temperature, severe pressure, acting slowly, should be caused by ice, the latent heat developed at the point of contact would tend to soften the ice and relieve the pressure. In special cases, allowance for ice pressure may be desirable, but, in most instances, no special allowance is necessary. Any possible ice pressure will be sufficiently cared for by the usual factor of safety of about two.

Before constructing the resultant pressure curve, a load curve should be assumed for the gravity action of the individual horizontal sections into which the dam is assumed to be divided. The assumed load curve should be such that the moments would show practically no tension in the up-stream face of the dam; and such that the greatest efficiency will result in the resisting forces on the principle of least work. Two or three trials will probably be necessary to obtain the best results.

For convenience in interpreting results, a percentage curve can be used, by constructing, to a convenient scale, a rectangle on the back of the section of the dam, so that with horizontal lines drawn from each of the joints considered, the total length of the line or ordinate will represent 100%, or the total load on each joint. The best percentage load curve for gravity action will not be a vertical line, but a curved line. The center of pressure for each horizontal section into which the dam is assumed to be divided must be determined, in order to obtain the moments from water pressure. The depth of the center of pressure for each section, from the surface of the water or top of the dam, can be determined by the well known formula,

$$\text{Depth from surface} = \frac{2}{3} \times \frac{d_1^3 - d_2^3}{d_1^2 - d_2^2}$$

in which d_1 = depth from the surface of the water to the top of the section considered, and d_2 = depth from the surface of the water to the bottom of the section considered. By subtracting the result obtained by this formula, from the height of the dam, or from the distance from the base of the dam to the surface of the water, the moment arm for each section, with center of moments at the base of the dam, will be given. These moment arms grading off gradually for equal heights of section, are easily checked by first and second differences—second differences for the upper half of dam, and first differences for the lower half.

It will be convenient to have first, the moments of the water pressure at each section for the total water-pressure load, from which the moments for the percentage load curve easily follow. It will be helpful in checking to remember that with the center of moments at the base of the dam, the moment of water pressure is greatest at the center of the dam—the moments grading off gradually toward the top and equally from the center toward the base.

When the percentage load curve has been adjusted so that the overturning moments do not produce appreciable tension in the up-stream face of the dam and the resultant pressure curve for gravity action has been constructed, the extreme fiber stresses in the down-stream and up-stream faces of the dam at each joint can be determined from the nearest edge distance from where the resultant pressure curve cuts the joint.

The well known general formula for the greatest unit pressure is:

$$p = \frac{2N}{d}\left(2 - \frac{3e}{d}\right)$$

in which

p = the greatest unit pressure;
N = the normal component of all the external forces acting; and
d = the depth of the joint, or thickness of the dam at the joint.

This general formula can be simplified considerably for special cases.

Having found for each section the maximum unit fiber stress, which will be generally at the down-stream face of the dam, the unit stress in the opposite face follows by substituting for e, in the formula, the longest edge distance from where the resultant pressure curve cuts the joint, or from similar triangles, assuming, of course, that the stress varies uniformly across the section. If the resultant pressure curve falls outside the "middle third", the opposite face stress will be tension.

Assuming a suitable elastic modulus for the concrete and considering the bottom section of the dam, the shortening of the down-stream and up-stream faces resulting from the compression can be found in the usual way; or, a little easier, by taking the difference between the compression at the down-stream and up-stream faces of the section, the shortening that would cause deflection at the top joint of the section easily follows. The deflection equals the shortening multiplied by the height of the section divided by the thickness of the base. This deflection of the bottom section only can be extended by simple proportion up through the different sections and to the top of the dam.

Proceeding to the second section from the bottom, the deflection of this section from the normal to the bottom section can be determined in a similar manner. Similarly, the deflections throughout the height from all the individual sections can be determined. The algebraic sum of all the different sectional deflections will give the total deflection at the different elevations of the gravity section.

If the resultant pressure curve near the top of the dam falls on the up-stream side of the center line of the dam, owing to differences in batter on the up-stream and down-stream faces of the dam, the top sections, where the resultant pressure curve is up-stream from the center line of the dam, will have a slight minus or up-stream deflection. This, however, is greatly overshadowed by the much larger down-stream deflections of the individual sections lower down. So that the resultant deflection curve with reservoir full will be generally down stream from the normal. When the reservoir is empty, there is an initial up-stream deflection to be considered, as the unit stresses

from weight will be greater in the up-stream than in the down-stream face, due to differences in batter in the two faces.

The deflections from arch action must be the same as in the gravity section, because they are in the same structure. Knowing the deflections, the corresponding unit stresses that would produce them can be determined from the deflection formulas of Silas H. Woodard, M. Am. Soc. C. E.,* or B. A. Smith, M. Am. Soc. C. E.,† by transpositions.

The Woodard formula is:

$$D = \frac{l}{2} \cot a,$$

in which,

D = the crown deflection;
l = the shortening of the arch ring under compression; and
a = one-quarter the subtending angle of the arch ring.

It will be found that although the actual deflections at the different sections vary greatly from top to bottom of the dam, a coefficient of deflection, that is, the multiplier of the unit stress, is nearly constant for the different sections and for the usual subtending angles, probably quite as nearly constant as the elastic modulus would be.

Short-cut methods, therefore, can be used in special cases. For instance, the writer found that for a dam with a radius of extrados of 275 ft., the deflection, in inches, was about 3% of the unit stress, in tons, for arch action. This gave a simple and quick way of comparing the results of variations in the load curve and dam section. If the deflections are known, the unit stresses easily follow and *vice versa*.

Deflection caused by drop in temperature can be investigated in a similar manner, if the temperatures of the different parts of the dam can be determined The author's suggestions for more data on the actual deflections of arched dams might well be applied also for more data of temperature measurements in dams. By means of the simple methods outlined, but with a few trials, almost any of the properties of any assumed section for a dam can be determined with a sufficiently close approximation for practical purposes. The accuracy of the well known cylinder theory as applied to thin cylinders unrestrained at the base is easily demonstrated. When applied to thick masonry dams, restrained at the base and in competition with more efficient resisting forces, however, it has its limitations. Nevertheless, the simple cylinder theory for arch dams is too useful for preliminary work and approximate estimates to be scrapped at present. It can be made simple and attractive by short-cut methods for application to special cases, for approximate results.

For instance, to illustrate its great simplicity of application in special cases: If the radius of the extrados of the arch is 320 ft., the stress, in tons, by the cylinder theory, at any horizontal arch slice 1 ft. thick, at a depth of h ft. from the surface of the water, would be, stress $= 10 \times h$. If the radius is 160 ft., it would be, $5 \times h$. This illustrates also the importance of as small a radius for the arch, as is practicable.

* "Analysis of Stresses in Lake Cheesman Dam", *Transactions*, Am. Soc. C. E., Vol. LIII (1894), p. 108.

† "Arched Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 2027.

Even for approximate purposes, the cylinder theory must be used with judgment and with low unit stresses in compression. If the unit stresses vary from a little less than 10 tons per sq. ft. to a maximum of not more than 20 tons per sq. ft., in the different horizontal sections of the dam, the results will probably be safe and not extravagant. However, more accurate methods for important matters should also be used in the interests of economy and certainty of results, as the author has suggested.

It has been intimated somewhere that wedge action is the chief resistance in the bottom portions of the arch dam. A curved wedge, however, is essentially an arch. The faces of the wedge cannot slide wedge-like on the sides of the valley, but are cemented to the rock. It is as logical to assume, in pure horizontal arch action, that the bottom horizontal arch slices are free to slide on each other, as to assume that the slices higher up are free to slide. Practically, none of them actually does slide and cannot slide. Shearing strength is sufficient to prevent that. The fact is that arch action in the bottom portions of the dam is outclassed by more efficient resisting forces.

The writer is of the opinion that tension in the up-stream face of arched dams should be limited to a maximum of about 50 lb. per sq. in. Generally, the dam would be cemented into the rock bottom at the up-stream edge to a depth of several feet, which would give some shearing resistance and permit a small allowance for tension in the up-stream face. It should be noted that there is comparatively little opportunity for arch action, until there is a little tension in the up-stream face of the dam. The percentage of the load that would be carried by arch action depends on the conditions. Without tension, however, in a extrados of 275 ft. radius, considered by the writer, it would be about 70% at the top, dropping rapidly to about 10% at mid-section and to less than 1% near the bottom.

Arch action is most efficient at the top of a dam. Cantilever action is least efficient at the top. Simple vertical beam action, by carrying some bottom load to the upper horizontal arches as well as much more into the rock bottom, utilizes arch action where it is most efficient. Gravity action is the most efficient in all the middle sections and takes care of much the greater part of the load. Where the cross-section of the valley is of a rather flat V-shape, flattening out at the top, it will generally be economical to locate a portion of the ends of the dam on tangents to the main central arch. The radius of the arch should be made as small as practicable, the stress being directly proportional to the radius.

Shortening the radius of a dam of the constant radius type tends to bring the ends around parallel to the contours on the sides of the valley. Making a portion of the ends on tangents to the main central arch tends to cut the contours more nearly at right angles and shortens the dam. These tangents, of course, should be of full gravity section; but if the top of the arch dam has a substantial, or practically full, gravity section, it would work in nicely on the shallow ends.

The constant radius dam with tangent abutments is an approach toward the ingenious "constant angle dam"* of L. R. Jorgensen, M. Am. Soc. C. E.

* *Transactions*, Am. Soc. C. E., Vol. LXXVIII (1915), p. 685.

The "constant angle dam" will generally be more economical of material; but as nearly all the surfaces up stream and down stream are substantially warped surfaces, the construction difficulties are slightly greater and the appearance generally less pleasing. The "constant radius dam with tangent abutments" is between the "constant radius dam" and the "constant angle dam", and is likely to be the most satisfactory in many cases, all things considered.

Topographical conditions, of course, would determine the most suitable type of dam for any particular location. As the radius of the arch increases, due to topographical conditions, the reduced gravity section approaches the full gravity section, and when the radius is much more than 300 ft., or the length is more than would be subtended by an angle at the center of about 120°, a full gravity section would probably be advisable.

There is no question but that a straight gravity dam, with good design, good materials, and good workmanship, can be made entirely safe. If the arched plan costs materially more, due to increased length, or any other reason, it could not in general be justified. If, however, the arched form costs no more than the straight gravity dam, it would undoubtedly be justified, as giving an added insurance against failure, because if, for any reason, gravity action fails, arch action stands by, competent to do the work. Ordinarily, however, arch action does not get much opportunity to work until there is some tension in the up-stream face of the dam. This is particularly true for the bottom portions where arch action is surpassed and greatly relieved by more rigid resisting forces.

The writer trusts that the author's appeal for data on the deflections of dams will produce results, and that he will continue his good work in developing and simplifying mathematical expressions for the properties of arch dams. Measured deflections to be of value must be taken with great accuracy. The striking feature about the matter is the relatively minute deflections compared with the enormous forces involved.

L. Standish Hall,* Assoc. M. Am. Soc. C. E. (by letter).—The writer has been impressed by the efforts made in the last few years to improve the theory used as a basis of the design of the arch dam. There is probably no engineering structure, considering the magnitude, in which precedent plays such an important part in the design. The formula that is most generally used in proportioning an arch dam, is the so-called cylinder formula. A brief comparison of the conditions under which this formula is applicable with those existing in an arch dam, will show that it is materially defective.

However, many dams have been designed by the cylinder formula, and the principal arguments to support its use are the ease with which it may be applied and the fact that no arch dams designed by it have failed. The fact that these dams have been designed according to a defective formula does not necessarily infer that they are unsafe. A large "factor of safety" is usually allowed so that the unit stresses in the concrete are much below those used in building construction where the distribution of the stresses can be calculated more accurately.

* Asst. Engr., H. L. Hachl, San Francisco, Calif.

A few years ago, the writer made a study of the arch dam and arrived at conclusions, quite similar as regards the requirements of formulas to cover the actual static conditions as those developed by Mr. Noetzli. It is believed that the author's method is sound from a theoretical standpoint, although with such a structure as an arch dam, in which static conditions are so completely indeterminate, it would appear to be impossible to develop from theoretical considerations alone, formulas that will apply accurately to actual conditions.

Real progress can only be made in the method of designing arch dams by securing more deflection measurements and other tests on existing structures, so that sufficient data may be collected to enable engineers to modify the theoretical formulas (in case such modification is found to be necessary) by certain empirical coefficients derived as the results of tests. The collection of such data could probably be best undertaken by some department of the State or Federal Government. Such observations would be assured of greater standardization in method and a greater uniformity of results.

The writer has not seen typical cross-sections of dams designed according to the author's principles. It is believed that such a presentation is essential to a clear understanding of the variations between his methods and the results obtained by the cylinder formula. It is understood that the cross-section of an arch dam will vary with the height and radius, but if the cross-section of some existing dam were shown, together with a design by the author for the same location, an interesting comparison could be made. The Barren Jack Dam or the Salmon Creek Dam which were shown, might be used in making such a comparison, and the writer hopes that the author will include some such presentation in his closing discussion.

WILLIAM A. MILLER,* ASSOC. M. AM. SOC. C. E. (by letter).—The writer has been much interested in Mr. Noetzli's further contribution to the literature on arch dams. Throughout, it is clear that one aim of the author is to place before the Profession a solution of the arch dam problem, as accurate as possible, without involving laborious algebraic or graphical operations. Although the writer has not especially considered the arch dam, he has studied the arch rib as a structural element from this same aspect, and he will contribute to the discussion of this paper by quoting the results of those portions of his investigations that are relative to the application of the arch rib as met with in the arch dam.

If the same assumptions are made in the derivation of Equation (17) as in arriving at Equation (10), then Equation (17) should read:

$$H_t = \frac{c\,T\,l\,E}{\int y^2 \frac{d\,L}{I} + \int \cos^2\alpha \frac{d\,L}{A} + 3\int \sin^2{}_1\alpha \frac{d\,L}{A}} \quad \ldots\ldots\ldots\ldots (23)$$

for the displacement of the point of application of H_t (that is, Point O' in Fig. 7 *b*, of Mr. Noetzli's paper, "Gravity and Arch Action in Curved Dams")†

due to temperature rise $= c\,T\,l$, and, due to H_t acting at O', the bending moment at $(x\ y) = M_x = -H\ y$, the axial force at $(x\ y) = N_x = H \cos \alpha$, and the shearing force at $(x\ y) = S_x = -H \sin \alpha$, giving the displacement of O' due to M_x as,

$$\int M_x\, y\, \frac{d\,L}{E\,I} = -\int H_t\, y^2\, \frac{d\,L}{E\,I},$$

due to N_x as,

$$\int N_x \cos\ \alpha\ \frac{d\,L}{E\,A} = -\int H_t \cos^2\ \alpha\ \frac{d\,L}{E\,A},$$

and due to S_x as,

$$\frac{6}{5}\int S_x \sin\ \alpha\ \frac{d\,L}{G\,A} = -3\int H_t \sin^2\ \alpha\ \frac{d\,L}{E\,A},$$

where G is the rigidity modulus of the material, and taken here for concrete $= 0.4\ E$.

As the displacement of O' is zero,

$$c\,T\,l - \int H_t\, y^2\, \frac{d\,L}{E\,I} - \int H_t \cos^2\ \alpha\ \frac{d\,L}{E\,A} - 3\int H_t \sin^2\ \alpha\ \frac{d\,L}{E\,A} = 0$$

or,

$$H_t = \frac{c\,T\,l}{\int y^2\, \frac{d\,L}{E\,I} + \int \cos^2\ \alpha\ \frac{d\,L}{E\,A} + 3\int \sin^2\ \alpha\ \frac{d\,L}{E\,A}} \quad \ldots\ldots\ldots (24)$$

which for the constant, E, would take the form shown in Equation (23). It is to be noted that the denominator of Equation (24) is the displacement of O' due to unit load acting at O' and in the line of action of H_t; it is independent of the loading on the arch. The numerator is the displacement of O' due to the applied loading or, as in this particular case, temperature change, that is, if R is the displacement of O', due to any loading whatever, then the thrust is,

$$H = \frac{R}{\int y^2\, \frac{d\,L}{E\,I} + \int \cos^2\ \alpha\ \frac{d\,L}{E\,A} + 3\int \sin^2\ \alpha\ \frac{d\,L}{E\,A}} \quad \ldots\ldots\ldots (25)$$

It will be clear that the author's coefficients, k_t, are slightly in error. Fig. 12 shows the percentage error involved. The writer presents the foregoing, not with the idea of emphasizing small matters, but rather to make clear what follows. Considering the writer's Equation (25) to give the accurate value of the thrust, then,

$$H = \frac{R}{\int y^2\, \frac{d\,L}{E\,I}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

when deformations due to axial and shearing forces are neglected;

$$H = \frac{R}{\int y^2\, \frac{d\,L}{E\,I} + \int \cos^2\ \alpha\ \frac{d\,L}{E\,A}} \quad \ldots\ldots\ldots\ldots\ldots (27)$$

when only shearing force deformations are neglected;

$$H = \frac{R}{\int y^2 \frac{d\,L}{E\,I} + 3\int \sin^2 \alpha \frac{d\,L}{E\,A}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (28)$$

neglecting only axial force deformations; and using the approximation in Mr. Noetzli's Equation (17),

$$H = \frac{R}{\int y^2 \frac{d\,L}{E\,I} + \int \frac{d\,L}{A}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

For the rib as found in the arch dam the form in Equation (29) is equivalent to using Equation (25), but substituting unity for the coefficient, 3, of the third term of the denominator.

Let l = span;

r = the ratio, $\frac{\text{rise}}{\text{span}}$, expressed as a percentage;

p_{26} = the percentage over-estimate of the value of H using Equation (26);

p_{27} = the percentage over-estimate of the value of H using Equation (27);

p_{28} = the percentage over-estimate of the value of H using Equation (28);

p_1 = the percentage over-estimate of the value of H using Equation (29).

Let t_1 denote a rib having a thickness equal to 1% of the span, and let t_2 denote a rib having a thickness equal to 2% of the span, and, similarly, for other rib thickness; then Figs. 9, 10, 11, and 12 show values of p_{26}, p_{27}, p_{28} and p_1, respectively, for a series of ribs having values of r ranging from 10 to 40 and rib thicknesses varying from 2 to 10% of the span; the axes follow closely the axes used by Mr. Noetzli.

The diagrams call for little or no comment as they explain themselves. From Fig. 9, it is clear that flexural deformations alone should be considered, only for thin, high, rise ribs. Fig. 11 shows that the neglect of axial force deformations has little to commend it. Fig. 10 shows that including flexural and axial force deformations and neglecting those due to shearing forces gives percentage error in the value of thrust, almost constant for variation of rise, but increasing with increase of rib thickness. A study of Fig. 12, however, shows that a greater degree of accuracy is obtained by the use of Equation (29), which is the same as Mr. Noetzli's Equation (17). Not only does this expression give the closest approximation to the true value of the thrust, but the calculations are much simplified—a most desirable combination from the designer's viewpoint—for $\int \frac{d\,L}{A}$ replaces $\int \cos^2 \alpha \frac{d\,L}{A}$.

CHAUNCY WERNECKE,* ASSOC. M. AM. SOC. C. E. (by letter).—The author's appeal to the Profession to assist in obtaining all possible data regarding de-

* Associate in Civ. Eng., Univ. of Washington; Structural Designing Engr., Skagit River Power Development, Seattle, Wash.

flections, temperature variation, and conditions of existing single arch dams should receive active support. Sufficient measurements on arch dams should go a long way to establish a more accurate method of design. Having such data, effective guidance could be given to further research with models. The degree to which the principle of similitude would apply, and the limiting size of models for reliable results, could be determined. Having thus established the reliability of models, the design of important structures might well be made from them, and the influence of the shape of the canyon could be determined in a most complete manner. The by-product value of such work would be considerable in any particular case. Such a method of design might seem costly at first, but in view of the possible saving in important structures, the extra expense would be well invested. Handling the problem in this manner would go far toward establishing faith in the economical arch dam.

There are two factors extraneous to scientific considerations in the design of an arch dam: First, a psychological factor resulting from lack of knowledge, and, second, a political factor injected when there are active opponents of the project in the community. The first consideration is partly basic to the second. Engineers lack knowledge as well as others. It is not to be expected that the knowledge and faith in the arch, as applied to bridges and buildings, will quickly transfer to a different use. It is to be expected that, even for an engineer or architect whose knowledge of the arch is extensive and whose faith in it is great, it will take some time for the same state of mind to form about the arch dam. For the average citizen, a proper faith in an arch dam would have to be carefully formed by well designed and honest propaganda. Otherwise, the second factor might cause considerable damage or delay to a project entertaining the use of such a structure. Such was the experience in 1904, with the Six-Mill Creek Arch Dam* for the water-works of Ithaca, N. Y., wherein the design afforded sufficient reason for a political filibuster to obtain public ownership of the water supply, and to reduce the dam from 90 ft. in height to 30 ft. The proportions of the Six-Mill Creek Dam were approved by a board of consulting engineers, but this had little effect.

It would seem advisable to initiate a co-ordinated research which might well begin with a thorough and impartial examination of arch dams. It is gratifying to note the interest in the subject, as measured by the space given it in the publications of the Society and other scientific journals.

W. H. R. Nimmo,† Assoc. M. Am. Soc. C. E. (by letter).—The papers recently presented by Mr. Noetzli have brought out many interesting points bearing on the design of arch dams, and the solution of the circular arch under water loads by William Cain, M. Am. Soc. C. E.,‡ is also a valuable contribution on the subject.

The writer recently had occasion to attempt the elastic analysis of the stresses in a proposed high arch dam, but arrived at the conclusion that the inaccuracies in the assumptions, which were necessary, rendered any numerical results valueless for the purpose of practical designing. For the same reasons,

* *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 183.
† Asst. Civ. Engr., Hydro-Elec. Dept., Hobart, Tasmania.
‡ See p. 233.

the writer is unable to accept the startling results arrived at by the author and, in the absence of definite evidence from observations, is not convinced that most arch dams are cracked.

Most investigators have adopted the method of equating the deflections of elementary horizontal arches and vertical cantilevers in order to find the proportions of water load carried by the two systems, the stresses in each system being then investigated separately. The method neglects other possible systems whereby part of the water load may be carried, but this probably causes an error on the side of safety and valuable results might be obtained if no other errors crept in. Unfortunately, the assumptions usually made, neglect, or do not accurately allow for, the following considerations:

(1).—Temperature variations, which are both uncertain in amount and irregular in distribution, the temperature in the body of the dam lagging behind the atmospheric temperature and this time lag is not the same at all levels in the dam.

(2).—Shrinkage due to setting of concrete.

(3).—Swelling due to soaking of concrete at the up-stream face.

(4).—Yielding of foundation due to eccentric vertical loading.

(5).—Yielding of foundation horizontally.

(6).—Yielding of abutments.

(7).—Deformation due to shear in cantilever.

(8).—Ordinary theory of flexure not strictly applicable to a triangular cantilever.

(9).—Cantilever assumed to be contained between parallel instead of radial planes. In a constant angle arch dam, the thickness at the lower levels becomes a large proportion of the radius, and this assumption involves considerable error in the value of the moment of inertia of the cantilever.

(10).—Formulas generally used for deflection of arch are not applicable when the arch thickness becomes appreciable in comparison with the radius.

(11).—Modulus of elasticity not the same for tension and compression.

(12).—Modulus of elasticity is not constant, but increases with the stress.

(13).—Effect of time factor in permitting increased deformation in the concrete.

(14).—Effect of lateral deformation.

(15).—Wedge action near base.

(16).—Possible arching in inclined planes.

Many of these points have been brought out in the previous discussion.

The effect of Assumptions 3, 4, 5, 7, 8, 9, 12, 13, and 14 would be to increase the deflection of the cantilever, and the combined effect may be sufficient to account for the differences in deflections as calculated by the author's method and as observed in existing arch dams.

By further complicating the calculations, it would be possible to develop a theory including the effects of Assumptions 7, 8, 9, 10, and 14, and the effects of yielding of foundation and abutments might be allowed for approximately. The effect of wedge action near the base and inclined arching, the writer believes, would be to relieve the horizontal arches and cantilevers, and a theory which neglects these, might still be of practical value.

The effects of Assumptions 1, 2, 3, 11, 12, and 13 are of prime importance and cannot be neglected, but, unfortunately, engineers are lamentably ignorant regarding them. Even if they could be accurately taken into account and the proportions of the load carried by the arches and cantilevers at the crown, at a given temperature, accurately determined, the difficulty would still remain, that these proportions would not hold for any other part of the dam, even at the same temperature. In reality, the load on the arches is not a uniformly distributed load, but an irregular one, which also varies with the temperature.

If an entirely satisfactory method of obtaining the stresses in an arch dam was available, it would be possible to design arch dams as reinforced concrete structures, which possibly would be more economical than dams of plain concrete. There is great need for more extensive observations on existing arch dams, including measurements of temperature, deflections, and strains, supplemented by further laboratory tests on concrete mixtures in regard to their elastic properties. When sufficient data of this kind are available, reliable formulas for the more economical design of arch dams may be developed. In the present state of the knowledge, it is probable that responsible engineers will continue to design arch dams on the assumption that the arches carry all the load, and it is for the purpose of more nearly realizing this condition that the system of grouting joints under pressure has been introduced.

The principal objection to the pressure grouting of joints arises from a belief that uneven filling of the joints will cause eccentricity of the arch thrust, which will result in dangerous bending moments. Although it is not probable that the grouting of joints can be made 100% efficient, it should be possible, with sufficiently close spacing of the grout pipes, to insure that such air pockets as might remain, would be small and well distributed over the cross-section, in which case, no appreciable eccentricity of the thrust would be caused. A small increase in the intensity of the arch thrust at the joint might result, but this would not be serious, and it is likely to arise, even if the joints are not grouted, from débris falling into the joints while they are open. In a dam, the joints of which open and close periodically, the effect of varying temperatures in the lower arches, combined with the resistance of the cantilevers, will cause the upper arches to close on slightly varying alignments, unless they are accurately keyed at the joints. In other words, the keys will be carrying shear stresses before the joints in the upper part of the dam have closed, which means that the surfaces of the keys may be sliding against each other under pressure, and this is certainly not a desirable condition. If satisfactorily carried out, there can be little doubt about the advantages of grouting joints under pressure.

In dealing with the deflections of the Salmon Creek Dam, the author finds, by subtracting the deflection at Elevation 1095 from the mean of the deflections at Elevations 1075 and 1115, that the cantilever has suffered a deflection of 0.18 in. in a length of 40 ft. The method of measuring the deflections has not been described in detail, but if they were made by angular measurements with an ordinary transit instrument, reading to, say, 10″ of arc, they may easily be in error by ± 0.05 in., in which case the 0.18 in. previously mentioned, may be greatly in error.

GARDNER S. WILLIAMS,* M. AM. SOC. C. E., AND ALBERT E. GREENE, ESQ.† (by letter).—At the time Mr. Noetzli's interesting paper was published, the writers were engaged in designing an arch dam about 85 ft. high and of 325 ft. radius. The available literature on the subject had been studied, various designs of thin arch dams had been examined, and the conclusion had been reached that the usual method of designing by the formula, $T = P\,R$, was not even approximately correct and that all existing thin arch dams of considerable span that are not anchored to the rock by reinforcing, must have opened a horizontal joint at the base. The deflection measurements of the Barren Jack and the Salmon Creek Dams seem to prove the failure at the base, beyond question. As it was not desirable to attempt to fix the base of the proposed dam, it was decided to make a hinged joint there and to allow the dam to rock freely with the imposition of the water load and, particularly, under changes of temperature. The site is in a gorge with a level bottom, and the arch dam is sprung between vertical abutments at the side-walls. For this particular condition, the stresses in a dam of any chosen cross-section can be computed readily.

The dam is assumed to consist of a system of vertical needles supported by a system of horizontal arch ribs, as shown in Fig 13, the assumption made by every one who has attempted a solution of the problem, as far as the writers are aware. Because of the long radius and the consequent thickness of the dam, the needles of the design in question are much more rigid than the arch ribs and remain practically straight, transmitting excesses of pressure from one arch to another when the arches deflect under load. The deflection of any rib, therefore, is proportional to its distance above the hinge at the base and, as the unit stress in any rib is proportional to the deflection of that rib, the unit stress at any point of the cross-section is proportional to the distance of that point above the hinge; that is, the thrust in the arch dam is distributed over the section in the same manner as the stress is distributed, under positive bending moment, over that part of the section of a beam lying above the neutral axis.

FIG. 13.

To find the magnitude of the rib stresses, consider the equilibrium of one of the needles lying between two radial planes, 1 ft. apart, at the up-stream face of the dam where the radius is R. The needle is in equilibrium under the action of the water pressure, its own weight, the reaction of the arch ribs, and the reaction at the base. The two sides of the needle are cross-sections of the dam and are inclined to each other at an angle of $\frac{1}{R}$, and it is on these sides that the arch thrusts are actually applied, as shown in Fig. 14, and not on the face, as shown in Fig. 13. Let f be the normal unit stress on the cross-section at an elevation, y, above the base, and let f_c be its value at the crest. The component of f on the median plane of the needle, therefore, is

* Cons. Engr., Ann Arbor, Mich.
† Ann Arbor, Mich.

$\frac{f}{R}$, and on any elementary area of the cross-section dA distant y above the base, there is a force of $\left(\frac{f}{R}\right) dA$ opposing the water pressure. Taking moments about the lower end of the needle or the base of the dam and equating the overturning moment of the external forces to the resisting moment of the components of the rib stresses in a manner similar to that followed in deriving the expression for the moment of resistance of a beam, since $f : y = f_c : h$, we have,

$$M = \int_0^h \frac{f}{R} y \, dA = \frac{f_c}{R h} \int_0^h y^2 \, dA = \frac{f_c I}{R h}$$

or, the arch stress at the crest is,

$$f_c = \frac{M h R}{I}$$

in which I is the moment of inertia of the vertical cross-section of the dam about an horizontal axis at the base, and M is the moment of the external forces, the water pressure, and the weight of the structure, acting on a vertical slice of the dam 1 ft. wide at the up-stream face.

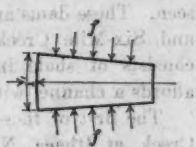

FIG. 14.

It appears that the most economical section for a dam of this type is one with a large value of I and that, instead of making the crest narrow and increasing the thickness toward the base where the arch stress is zero, good designing will place as much material as possible near the crest. A wall of uniform thickness, therefore, is preferable to the usual trapezoidal section for dams of moderate height in a box canyon.

Attention must be given to the design of the needles which, if of the usual form, will require reinforcing on the down-stream face to prevent breaking. The line of thrust can be kept within the cross-section and the necessity of reinforcing obviated by curving the structure in the vertical plane, as one of the writers did in the Six-Mile Creek Dam.* Where reinforcement has been used in the past, the arches have been reinforced and not the needles which particularly need it, if the dam is to act as a monolith.

Temperature stresses in dams of this type were found to be of much importance, and they are undoubtedly so in all arch dams. In the design in question, it was computed that a change in the temperature of the concrete of 30° Fahr. would deflect the crest about twice as much as the water pressure alone, so that, assuming the dam to be built with expansion joints, which are to be filled in cold weather, the dam might be expected to deflect up stream in the summer with full pond, as far as it would deflect down stream in winter, both deflections being measured from the unstressed position.

The formulas developed for this dam placed between two vertical abutments should not be applied to thin arch dams in a valley with sloping sides. Writers who have attempted an analysis of the general problem have assumed

* *Transactions*, Am. Soc. C. E., Vol. LIII (1904), p. 183 *et seq.*

that every arch rib carried a uniform radial load. As the water pressure on any rib may be carried in part by that rib and may be distributed in part by the needles to other ribs, there is no good reason for thinking that a given rib is uniformly loaded, except in the case where all the needles are of the same length.

An attempt was made to analyze the two dams the deflections of which are discussed by the author, on this basis, and it appeared that the needles were not strong enough to distribute the water loads between the various ribs. It is believed that the upper arches of a dam in a V-shaped valley are relieved of part of the load which would be indicated by their deflections if the assumption previously mentioned was correct, because they do not take the form the computer thinks they should. For this reason, the writers do not wholly agree with the author in his conclusions about computing the stresses from the deflections. They, however, would congratulate him on this and his previous paper,* which are valuable additions to the progress being made in the analysis of arch dams.

While on the subject of arch dams, the writers would place on record some unusual examples which do not appear in any of the published lists they have seen. These dams are timber structures now or formerly existing on Taghanic and Six-Mile Creeks, near Ithaca, N. Y., where the geological formation consists of shale in horizontal layers with vertical fracture joints, which affords a channel with a level bottom and nearly vertical sides.

The first of these structures is the Van Natta Mill Dam on the Six-Mile Creek, at Ithaca, N. Y., which property was acquired by the Ithaca Water-Works Company in 1892. Previous to that, it had been used as a grist-mill and the dam had been in place for many years. The date of its construction is unknown to the writers. It continued in service until the great flood of June, 1905, when, with a head between 7 and 10 ft. above its crest, it was carried away.

The dam which rested on rock, consisted of a spillway between two masonry abutments. The spillway was 2.35 ft. thick, built of planks laid flat and spiked together and was anchored to the rock by iron rods about 10 ft. apart, extending several feet into the body of the work. The length of the crest of the spillway, on center line, was 90.25 ft., with a down-stream chord length of 86.4 ft. The north abutment was from 4 to 6 ft. thick, whereas that at the south was about 2.5 ft. thick and extended in a curve about 16 ft. to a vertical rock face against which it abutted, its height varying from 3 to 7 ft., of which 2 ft. was above the crest of the spillway. The up-stream radius was 100.66 ft. The crest of the spillway was inclined, the down-stream edge being 9 in. higher than the up-stream corner. For 56 ft. of its length, the spillway was from 17 to 18 ft. in height, and in the 16 ft. next the north abutment, the rock was inclined so as to give it a height of 12 ft. at that abutment. On the south, the rock inclined through the last 18 ft., giving a height of spillway at the abutment of only 5 ft. At the time of failure, the flow in the creek was more than 8 000 cu. ft. per sec., and the structure had withstood previous floods of more than half that quantity.

* "Gravity and Arch Action in Curved Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 1.

The second dam was built by the Ithaca Water Company in Six-Mile Creek about 600 ft. down stream from the so-called Six-Mile Creek Dam, and varied in height from 5.6 to 6.5 ft., had an up-stream radius of 109 ft. and a span of 94 ft., with an uniform thickness of 1.42 ft. It was built of two walls of 2 by 4-in. timbers, laid flat, with the intervening 9-in. space filled with concrete. It was anchored to the rock with rods about every 5 ft. This dam, which was in the gorge,* was in service four or five years and passed floods of 2 to 4 ft. over its crest. During the construction of the Six-Mile Creek Dam, about one-third of it was removed to drain the gorge and was later replaced. It was tipped over at the center and partly carried away in the flood of 1905, which passed over the dam above, with a head of about 10 ft. It is not known at what time during the flood this dam failed. The discharge of the creek during the flood was at the rate of more than 8 000 cu. ft. per sec., and this dam had withstood a flood of about 4 000 cu. ft. per sec., previously.

In 1904, one of the writers built the third dam which is across Taghanic Creek above Taughannock Falls and may be seen from the Lehigh Valley Railroad. The up-stream radius is 120.5 ft., the span 150 ft., the height is approximately 6 ft. throughout its length, and the thickness is 1 ft. It is built of oak plank laid flat and spiked together, and anchored to the rock by 1-in. bolts every 4 ft. Each alternate bolt goes to the crest, the others going through the sill only. They are set 1 ft. deep into the rock.

During a heavy flood in March, 1912, ice was brought down the creek in blocks 2 ft. thick and more, and lodged against the dam, and the head-water rose to a height of 5 or 6 ft. above the crest. The accumulated ice and water folded the dam over at its center, until the upper part of the section lay almost at right angles with the lower part. When the flood subsided, the deformed part was jacked back into position, a timber brace was set against its center and the structure continued in service.

Another structure which may be of interest in this connection, is Campbell's Dam in Cascadilla Creek at Ithaca, designed by one of the writers and built by the owners in 1904. It is of concrete, reinforced with miscellaneous iron and steel rods. The up-stream radius is approximately 70 ft., the crest is 29 in., and the base 4 ft. thick. The up-stream face inclines down stream 1 in. per ft. The length of the crest is 51.6 ft. at the down-stream edge. The abutments which are part of the arch and about 3 ft. above the crest, are 25 ft., and 11.3 ft. long at the crest level. For 35 ft. of its length, the dam is 25 ft. in height and decreases to 17 ft. at the south abutment, and runs to zero at the ends. This dam has had a flood of about 5-ft. head over it.

The Van Natta, Taughannock, and Campbell Dams were all near the crest of a fall, so that the back-water could not rise more than 2 or 3 ft. below, in any case. The dam of the Ithaca Water Company was undoubtedly submerged in the big flood.

F. A. Noetzli,† Assoc. M. Am. Soc. C. E. (by letter).—By a fortunate coincidence, the writer's investigations on arch deflections and stresses were

* *Transactions*, Am. Soc. C. E., Vol. LIII (1904), Plates IX and X, pp. 185, 187.

† Chf. Engr., Beckman and Linden Eng. Corporation, San Francisco, Calif.

published at the same time as a paper* on a similar subject by William Cain, M. Am. Soc. C. E. The writer concentrated his efforts on the development of simple methods and approximate formulas that might be more easily understood and used by hydraulic engineers engaged in dam design, whereas Professor Cain has effected, in a brilliant manner, the theoretically correct solution of the determination of the stresses in the arching parts of arch dams. A comparison between the two methods discloses the fact that in many cases results obtained by the writer's approximate formulas are almost identical with those obtained by the exact method of Professor Cain. In other cases, some discrepancy exists, as was naturally to be expected. However, the difference for true arches, within practical limits, is seldom great enough, that it could not be considered practically negligible when compared with the uncertainties involved in the assumptions as to the modulus of elasticity, degree of shrinkage of concrete, range of temperature, etc. The greatest discrepancy is found where the two methods are applied to thick and flat arches such as generally occur in the lowest parts of arch dams. It is questionable, however, whether any known arch formula can be applied to very thick arches without considerable modification. Professor Cain has shown, for instance, in an arch 40 ft. thick, of 135 ft. radius, and with a central angle of 40°, that only about 2½% of the radial load is supported by what is commonly understood as arch action. On page 249 of his discussion of Professor Cain's paper referred to previously, Mr. Mensch has indicated why such an "arch" cannot act as a horizontal beam, and the writer, on page 262 of his discussion of the same paper, has tried to illustrate the reasons why "secondary arch action" within the arch may interfere with true arching.

In any arch for which it is possible to inscribe, for instance, another arch of half the thickness and having a radius of less than half the radius of the primary arch, so-called secondary arch action is likely to occur. The reason for this lies in the fact that the stresses in the secondary arch are theoretically less than those in the primary arch for the same load, and Nature makes use of this fact by what is known as the "principle of least work". Not only one secondary arch is formed within the body of the primary arch, but a series of elementary arches, whereby the load can be supported with a minimum of elastic deformations according to the previously mentioned "principle of least work."

Furthermore, an investigation made by the method of combined cantilever and arch action will generally show that, in the lower parts of dams, arch action is very small, most of the load near the foundation being supported by the vertical cantilevers. These considerations unquestionably argue for caution in applying any kind of arch formula to the lowest parts of arch dams, and if such extreme cases are excluded, it will be found that the writer's approximate formulas given in his paper may well be used to illustrate the relation between deflections and stresses in arch dams.

In order to avoid misunderstandings, it may be desirable to fix some limits outside of which the approximate formulas cannot be expected to furnish other than rough approximations. In the writer's judgment, the deflection stress

* "The Circular Arch under Normal Loads", p. 233.

Formulas (1) to (9) should not be applied without modification to such arches for which the proportion between thickness and rise of arch is nearly unity or even larger, that is, for which, say, $\frac{t}{h} \geq 0.8$.

Mr. Mensch raises the interesting question of why an arch dam, in which according to the writer's theory the cantilever appears to have developed cracks, does not leak. Leakage is prevented by the weight of the masonry. Although a dam may have failed in gravity action and developed horizontal cracks at the up-stream face, the concrete near the down-stream side is under high compression. Therefore, cracks, due to bending of the cantilever, will hardly ever extend through the dam for this same reason. The conditions are different for circular reinforced tanks for which the vertical walls have not been tied adequately to the base to take care of the vertical bending moment. In such faultily designed tanks, the bending moment at the base of the thin and light vertical walls generally starts a crack, and uplift and shear do the rest, thus effecting a measurable movement between vertical walls and base, and leakage is almost certain to occur. In dams which may be from 30 to 40 ft. thick at the base and which are prevented from considerable movements by the relatively close vicinity of the side abutments, there is little chance for a crack to extend all the way through, as the weight of the masonry above will always tend to close a crack and seal tightly the down-stream part.

Mr. Mensch further asks why an arch, which according to the writer's approximate method ought to show serious defects, does not fail? It may be stated that the example to which Mr. Mensch makes particular reference is a rather extreme case,* that is, an "arch" for which the thickness is about 1.3 times the rise $\left(\frac{t}{h} = 1.29\right)$. Furthermore, it is to be considered that any formula, if applied to a hingeless, unreinforced concrete arch, gives reliable results only if the arch has no open cracks. If calculations show that excessive tension occurs in such an arch at certain places, so that cracks may be expected on the tension side, such cracks act statically as a kind of "hinge" and the basic assumptions for a hingeless arch are void and, therefore, also the formulas based on such assumptions. If a crack (partial hinge) which, for instance, may have opened due to a rise of the arch temperature when the reservoir was empty, is closed entirely by the pressure of the rising water, the arches may again be considered as hingeless for purposes of stress calculations, although, of course, the crack still exists.

To make this point clear, assume an arch dam with reservoir empty, and such a decrease of temperature that the construction joints have opened. Either Professor Cain's exact formula for temperature stresses, or the writer's approximate formula, or any other formula, would furnish, for such a decrease of the arch temperature, certain stresses at the abutments as well as at the crown of the dam. As the construction joints are open, it is evident that no

* Such conditions were referred to by the writer in "Gravity and Arch Action in Curved Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 134, to be examined by the exact theory of the elastic arch.

stresses can be transmitted through such open cracks, and both the crown and abutments of the arches may be without temperature stresses. However, due to the shortening of the arch sections resulting from the assumed drop of temperature, the two surfaces of each joint are turned in such a manner that they are no longer parallel. If the water rises and presses against the arches, the temperature being the same, the open joints will begin to bear unevenly against each other. For instance, at the crown, the parts farther up-stream may start to transmit the arch thrust from water pressure, while the joint may still be slightly open on the down-stream side. Eventually, the water pressure may be sufficient to produce compression over all the sections of the arch, and therewith the conditions for theoretical hingeless arch action are re-established, and the formulas apply for this condition although the arch is cracked.

Furthermore, it may happen that, in a solid unreinforced arch, the thrust has moved outside the middle third of the section and sometimes, theoretically, even outside the section itself. As soon as the tension produced by the eccentricity of the arch thrust is large enough to open a crack on the tension side, an artificial "hinge" is created and the arch thrust is automatically moved back and passes through the center of the "hinge". The assumptions as to hingeless arch, therefore, are changed for these conditions and the results from the formulas have to be interpreted accordingly.

Such considerations may clear some misunderstandings that certain members seem to have had from applying the formulas and conclusions of the writer with respect to the present conditions of certain arch dams. For arches that are adequately reinforced, the formulas apply within their limits of accuracy, without modification.

Professor Cain's numerical examples, by using his exact method and comparing the results with those obtained by the writer's approximate formulas, should prove instructive. Thus, the similarity of the results of respective calculations applied to the arch slice at Elevation 1115 of the Salmon Creek Dam is rather striking. The stresses at the crown were found to be:

	Cain.	Noetzli.
At the extrados, $f_c =$	468	461 lb. per sq. in. (compression)
At the intrados, $f_c =$	126	94 lb. per sq. in. (compression)

and at the abutments,

At the intrados, $f_c =$	656	645 lb. per sq. in. (compression)
At the extrados, $f_c =$	— 22	— 89 lb. per sq. in. (tension)

The difference between the two results appears to be slight if compared with the results obtained by the cylinder formula which furnishes, both at the crown and at the abutments, a uniform axial stress of 307 lb. per sq. in. (compression).

The point that the writer desired to bring out by the determination of the stresses from measured deflections was particularly to show the wide discrepancy between cylinder theory and actual conditions. It is immaterial, therefore, whether the results by the approximate formulas differ a few pounds per square inch from the theoretically correct values, as long as the apparent defects of existing arch dams may be brought, in an easily comprehensible manner, to the attention of engineers. In order to obtain more nearly correct

results by the writer's method, it would be necessary to determine the actual load on the arch by the method of combined cantilever and arch action. For illustrative purposes, however, the figures given may be considered as sufficiently accurate to arouse the interest of engineers in arch deflection stresses.

The writer is unable to agree with Professor Cain's interpretation of the part played by temperature deformations, if the stresses in an arch ring are to be determined from the deflections. The formula for the deflection, D, on page 316, seems to be incorrect as far as the part referring to temperature is concerned. This is evident from Fig. 18 (a) and Fig. 18 (b)* from which this formula was derived. It also differs considerably in its results from Professor Cain's exact formula for temperature deflections.

Furthermore, the writer questions whether the assumption of "dam simply supported at the base, with no bending moment there", will ever be valid in the case of high dams. Such a dam may have developed cracks and, therefore, a partial "hinge" near the center of the canyon, but such cracks hardly ever will extend all along the side abutments. Therefore, bending moments at the base are certain to exist in the vertical cantilevers nearer to the side-hills. Furthermore, the weight of the masonry of high dams will always exert a considerable moment at the base, which acts in an opposite direction to the moment produced by water pressure. The deflections of an arch are influenced materially, also, by the moment exerted by the weight of the dam and the neglect of this weight moment, made by the assumption of "no bending moment at the base", may lead to results more or less in error.

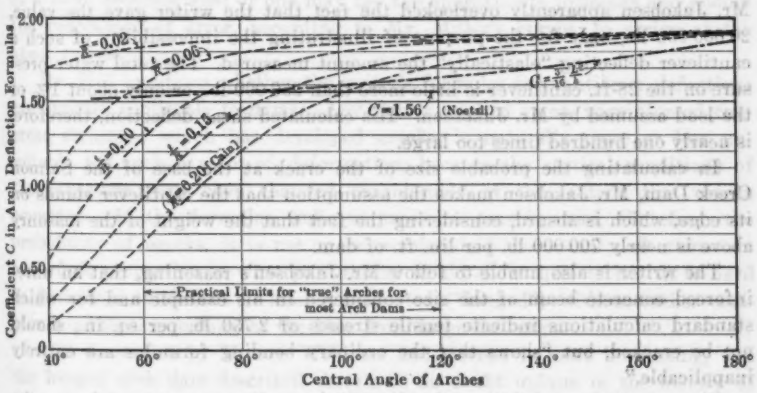

FIG. 15.

The theoretically exact deflection Formula (15) given on page 241 of the paper by Professor Cain, previously referred to, for which coefficients were given in his Table 1 (page 234), will be of great help in many cases. As a matter of comparison, those coefficients were plotted in Fig. 15, together with the coefficients, 1.56, and $\frac{3L^2}{16h}$, of the writer's approximate deflection formulas.

* *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 80.

It will be noticed that the difference is comparatively small for most arches of the upper parts of arch dams where free arching may occur. In cases where accuracy is of great importance, Professor Cain's exact coefficients should be used for calculating deflections, in preference to the writer's approximate formula. In the writer's opinion, both formulas should be applied with caution for very thick or flat arches.

The writer fully appreciates the excellent results arrived at by Professor Cain in his admirable paper on "The Circular Arch under Normal Loads". Engineers who desire to design arch dams with the utmost degree of accuracy, will find satisfaction in Professor Cain's formulas. Hydraulic engineers who prefer simple formulas, simply arrived at, may be satisfied to use the writer's approximate theory of arch dams. Occasional check calculations for critical cases, for instance, when the stresses, calculated by the approximate method, appear to be near the permissible limits, may be made by the exact theory and without unduly lengthening the procedure.

The writer is unable to appreciate the efforts of Mr. Jakobsen in calculating the influence of shear on the deflections of the Salmon Creek Dam. In calculating the angle at the base of the dam, Mr. Jakobsen assumes the cantilever as carrying all the load for the full height of the dam, and the arches nothing, whereas apparently the opposite is more nearly correct in this particular case. Therefore, Mr. Jakobsen's results are evidently greatly in error.

In the second example, relating to the short cantilever below Elevation 1035, Mr. Jakobsen apparently overlooked the fact that the writer gave the value, 20 000 000 lb., only for the purpose of illustrating the impossibility of such a cantilever deflecting "elastically" the amount measured. The total water pressure on the 28-ft. cantilever is little more than 250 000 lb., or only about 1% of the load assumed by Mr. Jakobsen. His calculated shear deflection, therefore, is nearly one hundred times too large.

In calculating the probable size of the crack at the base of the Salmon Creek Dam, Mr. Jakobsen makes the assumption that the cantilever stands on its edge, which is absurd, considering the fact that the weight of the masonry above is nearly 700 000 lb. per lin. ft. of dam.

The writer is also unable to follow Mr. Jakobsen's reasoning, that an unreinforced concrete beam of the size considered in his example and for which standard calculations indicate tensile stresses of 2 750 lb. per sq. in., should not be cracked, but "shows that the ordinary bending formulas are entirely inapplicable."

There is little probability of seeing, from a distance, the cracks on the warped down-stream face of the Salmon Creek Dam, at either Elevation 1075 or Elevation 1155, and this may be the reason why such cracks, apparently have not been discovered. At the upper elevation, the dam is only 11 ft. thick, and there is no reason to assume that a beam of this thickness should act so greatly at variance with theory, as Mr. Jakobsen would have one to believe. The fact that apparently no one has seen those cracks is not conclusive proof of their non-existence, and if standard calculations show, theoretically, tension stresses 10 to 20 times larger than average concrete is known to be able to stand without

breaking, the conclusion as to the occurrence of cracks would appear to be well justified.

Mr. Dunn deserves much credit for having called attention in such an able manner to the probability of uneven loading of the horizontal arches at certain dam sites. In fact, the writer has had the same experience in similar cases, and for this reason has suggested* that "in addition to the foregoing investigation of the cross-section of the dam near the arch crowns, in general it will be desirable to investigate also the sections at about the quarter points [or any other points] of the highest arches, * * *." The writer has come to the conclusion that in all cases for which the difference of the arch load at the crown and near the abutments is not very large, the maximum load may be assumed as acting uniformly over the whole arch. Rib-shortening and shrinkage have the tendency to move the arch thrust at the abutments toward the air side of the arch, thus approaching again more closely the circular form of arch axis. However, every dam site has its own peculiarities and no definite rules can be stated.

Mr. Miller's excellent presentation of the derivation of exact formulas for secondary arch stresses is noteworthy, and his curves which show the overestimate of the value of the deformation thrust, H, for the various approximations, will be of good service to designers. Thus, it is possible to judge from those curves whether, for an arch of given dimensions, the error involved by the use of an approximate formula is large enough to warrant the application of a more accurate one; or one may use the approximate formulas and deduct the percentage of error, according to Mr. Miller's curves, to arrive at the exact values.

Mr. Hill questions whether the writer's formulas for cantilever deflections are strictly applicable to dams. Any theory applied to an unreinforced concrete structure which has developed cracks, is naturally more or less unreliable for such a state of deformation, because the statical conditions of the structure may have changed considerably at the instant that cracks occurred. If the formulas indicate excessive tension, and, therefore, the probability of cracks, it is not to be wondered if the actual deflections are out of all proportion to what pure theory would show them to be. It is hard to imagine a thick dam as simply supported ("hinged") without rather complex conditions resulting at the base from large deflections.

The discussion by Messrs. Williams and Greene is most interesting, and the hinged arch dam described therein is no doubt unique in the history of dam design. For the particular dam site, that is, in a gorge with a level bottom, the provision for a hinge at the base of the dam appears to be a good solution, inasmuch as a horizontal crack would probably have developed there in any case, because the span of the arches is too long as compared to the height of the dam.

As a general rule, it may be stated that, in order to enable elastical cantilever and arch action in unreinforced dams, the span of the highest arches

* "Gravity and Arch Action in Curved Dams", *Transactions*, Am. Soc. C. E., Vol. LXXXIV (1921), p. 25.

should not be much more than about twice the height of the dam.* Otherwise, the vertical cantilevers have to be anchored by steel bars to bed-rock or to enlarged horizontal cracks near the foundation.

It has been claimed by some engineers that the usual methods of calculating the deflections and stresses in cantilevers do not apply to the vertical cantilever slices of arch dams. For thin and comparatively low dams, there is no reason why the standard methods of structural design should not be applicable with the same degree of accuracy as in building or bridge construction. For instance, the Barren Jack Dam is only 5 ft. thick at the base and 2 ft. thick at the crest, and the concrete is probably of the same quality as that in other structures, so that the same assumptions and laws may be applied. It is possible, however, that, for very high and thick dams, the usual assumptions as to Hooke's law, modulus of elasticity, etc., may have to be modified somewhat. The question is, how far and for what size of dam are such new rules to be applied. This can only be determined by tests.

Some engineers also rely, to a great extent, on the "flow" of concrete under high compression, and on the "time factor". The writer would suggest caution in applying such assumptions indiscriminately and before definite rules have been established by tests on dams. In the present state of knowledge, it would appear to be safer practice to calculate the stresses in arch dams according to the well established theories and assumptions used in the design of other concrete structures, and then make, if desired, a correction for flow, time factor, etc., of 10, 20, or 50%, or whatever may be judged to be reasonable for the particular structure in question.

Cantilever and arch deflection stresses of considerable magnitude are likely to occur in any arch dam, and such stresses should be taken care of, in addition to those resulting from pure cylinder action. In no case should designers of arch dams continue to imitate the ostrich which is said to bury its head in the sand in the endeavor to hide from a threatening danger.

One of the main purposes of the writer's recent papers was to arouse among hydraulic engineers more general interest with regard to true arch action in arch dams. Instead of following strictly theoretical lines, as others had done, he chose to simplify the various problems encountered by developing approximate methods and formulas that might be more easily understood and more readily applied, without the necessity of delving into all the intricacies of the theory of the elastic arch. Several exact methods of designing arches according to scientific principles were developed a score or more years ago. One of the main reasons why such methods have not been used more generally for arch dams is their complicated form which makes it difficult for the average engineer to study and apply these methods in the usual short time allowed for the design of dams. The writer hopes, therefore, that his approximate formulas may be of help to engineers as an intermediate step on the ladder to perfection.

Other cases are known in structural design where approximations are used extensively for the sake of simplicity. The most striking example is the present standard design of continuous girders, for which the coefficients of

* See also "Beitrag zur Berechnung massiver Staumauern", by Prof. A. Rohn, *Schweiz. Bauzeitung*, March 11th, 1922, p. 128.

$\frac{1}{8}$, $\frac{1}{10}$, and $\frac{1}{12}$ are used for calculating the bending moments, instead of the theoretically more exact but much more complicated "three-moment equation" by Clapeyron. Engineers versed in structural design are well aware that the difference between the approximate and the theoretical results is often 50% and more, particularly in the case of heavy live load on continuous girders of uneven spans. However, the approximate formulas are generally used, on account of their simplicity.

Paper No. 1485

THE FLOOD OF SEPTEMBER, 1921, AT SAN ANTONIO, TEXAS.*

By C. Terrell Bartlett,† M. Am. Soc. C. E.

With Discussion by Messrs. Charles W. Sherman, Allen Hazen, Edgar Jadwin, C. E. Ellsworth, and C. Terrell Bartlett.

Synopsis

This paper describes the flood of September 9th, 1921, in the San Antonio River, at San Antonio, Tex., and in several tributary creeks all of which traverse that city, the fundamental conditions of topography and climate, and the meteorological factors and hydraulic elements of the flood in so far as it was possible to determine them.

Before describing in detail the recent flood experienced by the City of San Antonio, and its engineering aspects, it will be well to outline briefly the principal geographic, topographic, and climatic features of the region.

Geographically and geologically, the State of Texas is divided into three grand provinces, as shown in Fig. 1. The first is the Rio Grande Plain, or Coastal Plain, an alluvial prairie extending from the boundaries of Louisiana and Eastern Oklahoma to the Rio Grande, and from the Gulf of Mexico inland from 150 to 200 miles. The topography ranges from the coastal flats through gently undulating and rolling country to altitudes of 400, 600, and 1 000 ft., along the inner margin of this region as one follows it from the Red River south and west to the Rio Grande.

The second of these great provinces extends from the margins of the Coastal Plain west to the Pecos River, the New Mexico line, and, northward, it embraces the Panhandle. This is the Central Plain, and forms the southern extension of the great plains of the Dakotas, Kansas, and Eastern Colorado. The third division known as Trans-Pecos Texas is part of the Rocky Mountain region.

* Presented at the meeting of October 5th, 1921.

† Cons. Engr. (Bartlett and Ranney, Inc.), San Antonio, Tex.

The line of division between the Rio Grande Plain and the upland plain or plateau is marked sharply and definitely by a great geologic fault which runs south about 300 miles from the Red River on the northern boundary of the State and thence swings west for 150 miles, where it crosses the Rio Grande into Old Mexico. This fault is known as the "Balcones Escarpment", and is characterized by a sudden rise in altitude from the Coastal Plain to the plateau region. At Del Rio, where this escarpment crosses the Rio Grande, the upper plain is about 1 200 ft. higher than the Rio Grande Plain, and the rise is very abrupt. In the vicinity of Fort Worth, the elevation is not more than 300 ft. and rises in a gradual incline across 15 to 20 miles.

FIG. 1.

The mean annual rainfall of Eastern Texas along the Louisiana line is 50 in. Thence, westward, it decreases to 30 in. along the eastern margin of the plateau, or Central Plain, and westward and southward to 20 in. at Del Rio and Brownsville. Although the influence of altitude is not apparent in the mean annual rainfall of Texas, it has long been recognized that in many cases the sudden rise at the Balcones Escarpment causes intense precipitation along and just above its margin. Due to the proximity of the Gulf, intense rains are also frequent along the immediate coast.

San Antonio lies in the Rio Grande Plain immediately below the Balcones fault zone, adjacent to the great angle where the plateau juts out into the plain. From the northern limits of the city, the country rises to the northwest for about 12 miles to the elevation of the plateau, 700 ft. above the general level of the city. On this sloping margin of the plateau are three comparatively small water-sheds the streams of which traverse the city and unite near its southern limits, as shown in Fig. 2. All the streams were in severe flood on the night of September 9th, 1921.

The City of San Antonio occupies 36 sq. miles and comprises a central valley the elevation of which is 650 ft. above sea level. It is bordered on the east and north by ridges about 100 to 150 ft. above the center of the city, and on the southwest by a slightly elevated plain. By the census of 1920, the population was 162 000.

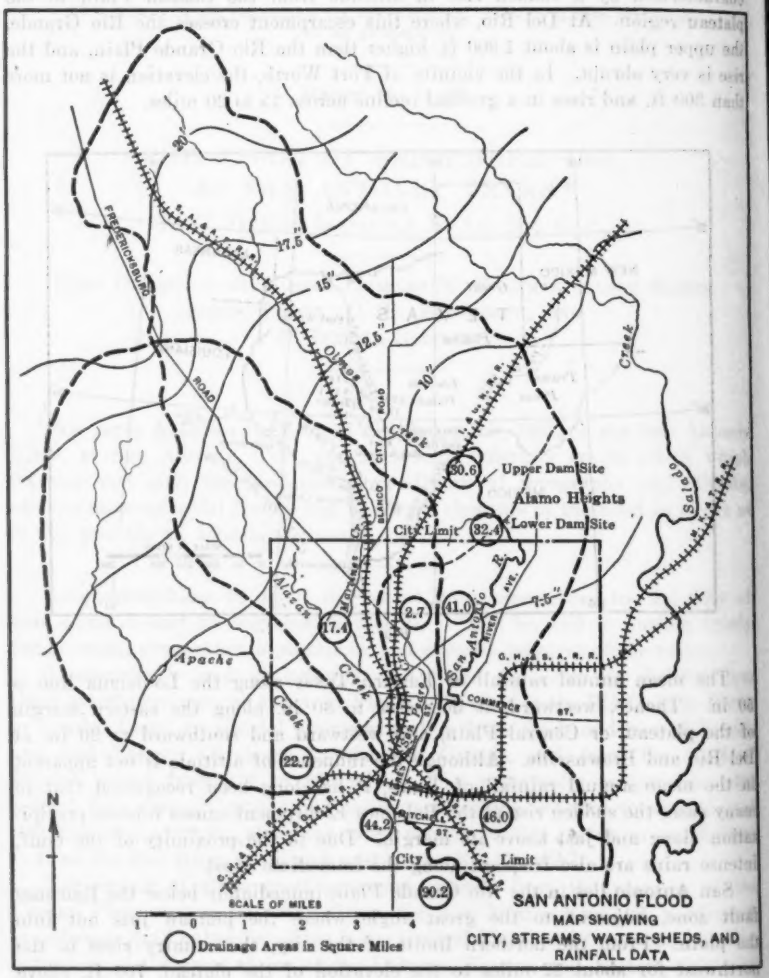

FIG. 2.

The San Antonio River rises from fissure springs near the northern city line, about a mile east of its center, and winds through the heart of the city within a well-defined flood-plain from ½ to ¾ mile in width. The flow from

these springs ordinarily fluctuates between 50 and 150 sec-ft. The length of the valley within the city limits is 6.3 miles, and the length of the river channel is 11.9 miles, with a fall across the city of approximately 90 ft. The greater part of the business district, some of the industries, and the older and more thickly settled residential districts, lie in the immediate river valley.

The largest of these three water-sheds tributary to the San Antonio River lies north of the city, and is drained by a watercourse known as Olmos Creek which ordinarily is dry. The Olmos water-shed is 32.4 sq. miles in extent which, with the lower area tributary to the river proper, makes a total area of 41 sq. miles above the center of the city.

Within the city and 2 miles north of its center, San Pedro Creek rises from springs the flow of which is seldom greater than 10 sec-ft. Above these springs is a small water-shed entirely within the corporate limits.

Above the successive confluences of Alazan and Apache Creeks, the San Pedro Creek has a tributary area of only 2.7 sq. miles, but when augmented by these watercourses, it has a total drainage area of 44.2 sq. miles where it empties into the San Antonio River near the southern limits of the city.

Both the Alazan and Apache Creeks are dry arroyos. The former enters the city from the northwest and has a water-shed of 17.4 sq. miles. The latter enters from the west and has a water-shed of 22.7 sq. miles, measured, in both cases, to their junctions with San Pedro Creek about 1½ miles south of the center of the city.

The Lower San Pedro traverses the western part of the business district, and, together with the Alazan and Apache Creeks, runs through some of the cheaper and more thickly settled residential districts, especially the Mexican quarter.

A drouth of several months' duration was broken on the night of Thursday, September 8th, 1921. San Antonio and the region to the north received a soaking rain, followed by occasional hard showers, during the day on Friday, September 9th.

Owing to the parched condition of the ground, no run-off occurred from the rain of Thursday night and only a little, except from areas within the city, from the day rain of Friday. The day rains of Friday were followed by a severe electrical storm, continuing from 6 P. M. to 9 P. M., during which the region north and northwest of the city was visited by intense rainfall which continued with reduced severity until 11:30 P. M.

Olmos Creek, north of the city, overflowed its banks and swept into the city about 10 P. M., reaching its crest within an hour. At the center of the city, the river, not more than 2 ft. above normal at 6 P. M., rose with increasing rapidity, overflowing its banks immediately north of the business district at midnight. Within an hour, a large part of the business quarter was inundated, and the crest was reached about 2 A. M. At this time, six of the principal north and south streets were channels carrying the swift flood waters across a great bend of the river. The water in these channels ranged in depth from 1 to 8 ft. where they crossed Houston Street, the principal east and west street, and at places in the business area the water was 12 ft. deep. North of

Houston Street, the water spilled through five streets over a low divide to the west into the Upper San Pedro Basin.

In the central district, the river rose from 2 to 8 ft. above all bridge floors and at each bridge a great mass of débris was caught by the piers and railings.

In the northern part of the city, the rush of water in the meantime had inundated Breckenridge Park along the river and all the adjoining low residential and industrial areas. Hundreds of homes were flooded to depths varying from a few inches to 8 and 10 ft. In this section, a few poorly built frame dwellings were washed away. A scum of heavy fuel oil from some of the industries coated everything it touched, and, incidentally, everywhere below left clear and unmistakable high-water marks. In the business district, all the basements were filled, and most of the first floors were flooded to depths of from a few inches to 12 ft.

The severity of the flood crest in the business district was undoubtedly somewhat mitigated by the pondage of water and its retention by houses and other obstructions in the valley above. In like manner, the obstruction formed by the business district, the storage of water in basements, and probably, also, a considerable absorption from the river channel into the gravel beds which underlie many parts of the valley, reduced the flood markedly below. This effect was partly counteracted as far as the flooded residence district just below the business section was concerned, due to two low dams and the blocking of two railway trestles with drift, all of which were situated about 1 mile below the center of the city. Below these obstructions, the flood was carried by the river channel and natural overflow bottoms which have not been encroached on by retaining walls and buildings to the same extent as in the central and upper parts of the valley. Notwithstanding many narrow escapes, there was practically no loss of life in the valley of the San Antonio River.

Owing to the comparatively light rainfall in the city, the small Upper San Pedro Basin did not flood badly, and its crest passed before the overflow from the San Antonio River. The latter inundated a number of buildings in the western edge of the business district, the water in it and the San Pedro forming a continuous sheet.

Alazan Creek, with a comparatively steep grade from the high ground northwest of the city, and its two branches flooding simultaneously, swept suddenly through the thickly settled low areas along its banks, playing havoc with bridges and tearing loose and destroying many cheap frame houses. It was in this section that the principal loss of life occurred. Conditions on Apache Creek were similar, but there was less development along its banks and the loss was smaller. Below the confluence of Alazan and Apache Creeks, the San Pedro again passes through a thickly settled area where there was considerable damage and loss of life. The total certain loss of life was 52, with 23 missing, most of whom were probably lost, making a total of 75.

The aggregate property damage was between $5 000 000 and $10 000 000. The greatest damage was to merchandise in flooded basements and on first floors. Next in amount was the loss in homes to clothing, furniture, and to the finish of walls and interiors from the muddy, oil-laden waters. The loss to the municipality was heavy, principally to pavements and wooden bridges

FIG. 3.—RIVER CHANNEL THROUGH HEART OF CITY.

FIG. 4.—RIVER CHANNEL THROUGH HEART OF CITY, DURING THE FLOOD.

FIG. 5.—SOUTH ALAMO STREET BRIDGE.

destroyed or injured, together with the expense of sanitary measures and for cleaning up the débris. One three-span concrete girder was destroyed by scour.

In general, substantial buildings were little damaged structurally, although there was a heavy loss of plate glass broken by water pressure and by drift, and, in total, a heavy damage for refinishing. The public service corporations suffered some loss, the principal item, however, being in decreased earnings for several days.

An interesting feature was the continuous low-pressure water service to the greater part of the city by the direct head of the artesian wells. An incident of engineering interest was the loss of practically all flooded wood block pavements which simply floated off. A large percentage of these blocks were gathered up, however, and relaid.

Several concrete basement floors were burst upward by pressure from water which traveled underneath, through gravel beds, before the basements were flooded from the top. On the first floor of buildings, tile floors, in several instances, were cracked loose at the joints, and the first-floor concrete slabs were undoubtedly severely strained by pressure from beneath. This occurred where the basements were flooded and the water in the streets stood from 2 to 3 ft. higher than inside the closed doors where the occupants were attempting to prevent its entrance.

The rain storm which caused the San Antonio flood was typical in that it broke on the margin of the Edwards Plateau. Rainfall data over the water-sheds above San Antonio have been secured by the writer and by the Engineer Corps of the Army. These data are based on records at about twenty points; about one-third were secured by standard rain gauges and one-fourth by measurements, in straight-sided cans, taken by farmers who keep more or less regular records. The remaining readings were secured by reducing measurements made in various classes of receptacles.

The testimony is so general as to the severity of the rain along the rocky rim of the Olmos water-shed and farther north in the plateau that there can be no question that at points the total precipitation was in excess of 20 in. Fig. 2 shows the total rainfall for the entire storm, from 6 P. M., Thursday, to midnight on Friday, a period of 30 hours. For the Olmos water-shed, the average rainfall was 14 in. and for that of San Antonio proper, below the city limits, it was 7.5 in., a mean depth of 12.5 in. for the entire basin.

The general storm over Central Texas was heavy, not only above San Antonio, but also at San Marcos and Austin, along the edge of the plateau. It is significant, however, that the heaviest rain, 19.5 in. in 12 hours or 23.1 in. in 24 hours, fell at Taylor, which is neither close to the coast nor adjacent to the plateau, but well out in the lower plain where previous statistics indicated that all the probabilities were against a rain exceeding 10 in. in 12 hours or 14 in. in 24 hours.

The available rainfall records of the general storm have been indicated on Fig. 1.

The greatest hourly intensities in the San Antonio storm were between 6 P. M. and 11:30 P. M. During this 5.5 hours, the rainfall ranged from 1.56 in. at the San Antonio Weather Bureau to 3.5 in., 4.5 in., 6.2 in., and possibly as

high as 15 in., at various points. The average on the water-shed for this 5.5 hours has been placed at 6.5 in.

The Engineering Corps of the writer's firm has made a hydrographic survey, as careful as circumstances permitted, of the slopes and areas of the flood crest at various points. It appears that ½ mile above the city limits, the flood peak in the Olmos was between 31 000 sec-ft. as a minimum, and 39 000 sec-ft. as a maximum, from 32.4 sq. miles. This represents from 960 to 1 200 sec-ft. per square mile. The peak discharge at the center of the city is estimated at 23 700 sec-ft., or 580 sec-ft. per square mile, from 41 sq. miles. Below the center of the city, 1½ miles, the crest is estimated at 1 500 sec-ft., or 333 sec-ft. per square mile, from 45 sq. miles.

The rapid reduction in flood crest both in total and in second-feet per square mile is significant in that the reduction was very much more rapid with increased area than would be indicated by the usual curves for second-feet per square mile. This was doubtless due in part to the distribution of the rainfall, but the influence of the river flood-plain in impounding the flow was also a marked factor. The influence of buildings probably increased somewhat this retardation over the natural conditions of a timbered flood-plain, although the streets were more efficient than natural channels. The average slope of the Olmos Valley above the city is 25 ft. per mile, the average fall of the river valley across the city being 14 ft. per mile.

One feature of the flood that will be difficult for Eastern engineers to understand is the comparatively small run-off. Above the city, the Olmos was not out of its banks more than 6 hours, the crest falling almost immediately. The flow increased from about 4 000 to 35 000 sec-ft. and fell again to 4 000 sec-ft., in 6 hours. At the center of the city, the flow ranged from 4 000 to 23 700 sec-ft. and back to 4 000 sec-ft., in about 11 hours.

From unofficial gaugings taken by the U. S. Geological Survey on the day following the flood, and by gaugings of the water-stage register, and from other data, a rough computation has been made of the run-off for the storm for a period of 7 days, which indicates that it did not exceed 10 000 acre-ft. from an area of 42 sq. miles above the station. All the storm flow had practically run off within the period of one week. It is unfortunate that the water-stage register of the Geological Survey was located at the South Alamo Street concrete bridge which failed. Although the gauge itself was undamaged and recorded the levels, except for 3 hours at the crest, the failure of the bridge interfered with the channel so that no accurate rating curve can be established for the flood conditions.

This estimated run-off of 10 000 acre-ft. is 36.4% of the depth of rainfall for the entire storm. However, by far the greater portion of this run-off was from 32.4 sq. miles above the city. It is probable, in fact, that the run-off was as great from the upper basin as from the entire basin, the absorption of flood-waters by gravel beds in the lower valley probably amounting to as much as the run-off from the lighter rain on the lower 9 sq. miles within the city.

Assuming that the run-off from the upper basin of 32.4 sq. miles was as great as at South Alamo Street, 5 miles down stream, that is, 10 000 acre-ft.,

FIG. 6.—ST. MARY'S STREET BRIDGE.

FIG. 7.—LOOKING NORTH ON NAVARRO STREET BRIDGE.

FIG. 8.—LOOKING TOWARD BUSINESS DISTRICT FROM PECAN STREET.

according to the estimate, the run-off from the Olmos Basin was about 42 per cent. Regarding the Thursday night and Friday rains, amounting to an average of 6.5 in., as producing only 10% of the actual run-off, there would have occurred an average run-off of not more than 70% from the 5.5-hour rain of Friday night falling on pre-saturated ground and amounting to from 3.5 to 15 in.

The flood peak on the Upper San Pedro Creek was not excessive either from the run-off of the earlier local storm, or from the later overflow from the river. The maximum discharge was possibly 1 500 sec-ft. from 2 sq. miles.

On the Alazan Creek the water-shed of which is ideal for a quick flood concentration and on which a small earth dam was washed out, the peak flow was approximately 33 000 sec-ft. from 16.9 sq. miles, or at a rate of 1 950 sec-ft. per square mile.

The Apache Creek is estimated to have flowed at a rate of 15 500 sec-ft. from 22 sq. miles, or 704 sec-ft. per square mile.

The average rainfall on the water-sheds of these two creeks was probably as high as that on the Olmos Basin and greater than that for the combined Olmos-San Antonio Basins. The flood peaks from the creeks reached the San Antonio River before its own crest so that although the flood experienced in the lower river was of unusual proportions, it was not of the extreme character suffered in the individual streams above their junction near the southern limits of the city.

San Antonio has been subjected to floods from its river and the western creeks at intervals of from 8 to 15 years. The last damaging floods occurred twice in 1913 and once in 1914. Spanish records tell of a flood in July, 1819, which was undoubtedly somewhat greater than the recent one. As a result of the floods of 1913-14, the city engaged Leonard Metcalf and H. P. Eddy, Members, Am. Soc. C. E., to report on methods of flood prevention, and their report filed in December, 1920, foretold the possibility of just such a flood as that which occurred.

As a result of the flood of 1921, a committee of local citizens and engineers was formed to study the conditions and make immediate recommendations on flood prevention, and it is probable that extensive works to that end will be undertaken.

The writer wishes to express his appreciation of valuable information secured from data collected in the report by Messrs. Metcalf and Eddy, to C. E. Ellsworth, Assoc. M. Am. Soc. C. E., of the U. S. Geological Survey, for advance stream records, and to Col. Edgar Jadwin, Corps of Engineers, U. S. A., for rainfall data and the opportunity of comparing discharge estimates.

DISCUSSION

CHARLES W. SHERMAN,* M. AM. SOC. C. E.—The information contained in this paper is of especial interest to the speaker because of his intimate connection with the preparation of the Metcalf and Eddy report to which Mr. Bartlett has referred.

This report embodied the results of a special study of local conditions, including such information relating to previous floods in San Antonio River as could be obtained, and a detailed examination of the records of intense rains in Texas and of the flood discharge of streams throughout North America.

As Mr. Bartlett has stated, floods which did considerable damage along the San Antonio River, occurred twice in 1913, and one which just escaped doing material damage occurred in 1914. Reasonably satisfactory information regarding these floods was obtainable, but data on earlier floods were extremely fragmentary and unsatisfactory. The dates of their occurrence and some approximation as to the height of the flood water at a few points were all that could be obtained, and much of this information did not become available until the investigation was nearly completed. Therefore, the estimation of the magnitude and frequency of serious floods had to be made on very incomplete information, and estimates of possible floods based on rainfall records proved of material significance in reaching the final conclusion.

The report recommended flood-control works for the San Antonio River, including an improved river channel with a capacity of 12 000 cu. ft. per sec. and a detention basin above the city of sufficient size to retain an additional 10 000 cu. ft. per sec., so that the complete works would care for a flood of approximately 22 000 cu. ft. per sec., or nearly three times the flood flow in 1913. This figure seems to have been very nearly the maximum rate of flow in the river during the flood of September, 1921.

The flood of 1913 was so much in excess of any other flood within the memory of the people of San Antonio that provision for a 50% greater flow in the river channel probably seemed to them to be adequate for the protection of the city. If the flood of 1921 had not occurred, local sentiment might not have followed the recommendations of the report to the extent of including the detention basin in the works to be constructed, although it is more or less probable that gradual improvement of the river channel to a capacity approximating that recommended in the report would have been carried out.

In view of the scarcity and unsatisfactory character of the information available, the conclusions of the report seem to be almost inspired prophecy, and it may be permissible to quote a few sentences showing how these conclusions were promptly and disastrously verified by the flood of September, 1921. The report states:

"We doubt if the citizens realize the ruinous loss which would result to-day with the present condition of the river channels, from such a flood as that of a century ago (1819). When such a flood will recur, no man can say. But that it will recur is certain. * * * We counsel the wisdom of pushing

* Cons. Engr. (Metcalf and Eddy), Boston, Mass.

this work, however, while the memory of recent floods is vivid, lest the public mind relapse into inaction in a false sense of security, only to be startled later by stern reality when the inevitable flood shall come. We urge that your citizens shall remember that this disastrous flood is just as likely to come next year as at any other time."

Remembering that this report was made in December, 1920, it appears that the prediction was verified within nine months of its presentation.

A report from the local Governor to the Provincial Governor, accounting for damages to Government property by the flood of 1819, appears in the county records. Texas was then a part of Mexico, which itself was a Spanish Colony. The property of certain rebels against the Government had been confiscated, including several houses of adobe construction. The flood water extended around some of these houses, which resulted in the softening of the walls so that the houses collapsed. It is impossible to say whether the water was 1 ft. or several feet deep, and there seems to be no information available regarding the condition of the stream channel. It is known that irrigation was practiced extensively, and it is possible that the diverting dams may have had considerable effect in raising the water surface. It is also probable that whatever bridges existed were of wooden trestle construction and may have seriously obstructed the flow of the stream. Exact knowledge of the flood height, therefore, would be insufficient as a basis for a satisfactory estimate of flood discharge. The report concluded that such discharge might have been between 20 000 and 30 000 cu. ft. per sec. Mr. Bartlett's conclusion is that the flood of 1819 was probably somewhat greater than that of 1921.

It is not impossible that the records of the old Spanish Missions, the earliest of which was founded about 1720, might also contain information of great significance in this connection. The speaker, however, does not know whether such records exist.

ALLEN HAZEN,* M. AM. SOC. C. E. (by letter).—This paper is a description of a most interesting flood. The writer had occasion to visit San Antonio shortly after the flood, and he read the paper carefully in connection with his own observations and commends the author for a concise and accurate statement.

In this case, the reason for anticipating a large flood had been pointed out professionally to the city by Messrs. Metcalf and Eddy, who had studied the conditions only a short time before. The lesson to be learned from this and other floods is that growing cities must give more attention to flood channels that are being closed by bridges, buildings, and encroachments of all kinds.

The San Antonio flood and other floods sometimes go so far beyond previous experience as to suggest that there is no law of flood frequencies, that governs. The writer does not believe that this view can be supported.

Engineers are learning more every year about the laws that govern the frequency of floods. Each new record helps. It may be expected that the continuous records of gauging stations will ultimately be more useful in establishing these laws than records of destructive floods that occur now and then where there is no continuous gauging. These extreme floods serve

* Cons. Engr. (Hazen, Whipple and Fuller), New York City.

to support and emphasize the conclusions that may be deduced from the study of records from regular gauging stations that much larger floods are to be logically anticipated at infrequent intervals.

There is a flood to be expected each year. There is a greater flood to be expected on an average once in 10 years, and there is a still greater flood to be expected on an average once in 100 years, and so on, and with innumerable intermediate steps. The chance is only one-hundredth of 1% that the 10 000-year flood will occur at any one place in any one year, but when the whole country is considered, some cities will suffer from such floods with a frequency well within the experience of human life, and the possibility of their occurrence at any place in any year must be taken into account.

The writer hopes that some day there will be evolved a much better basis for estimating these probabilities and for determining how much may be done in preventing them without, on the other hand, going to unreasonable extremes.

EDGAR JADWIN,* ESQ. (by letter).—This paper contains an excellent account of the San Antonio storm and its relation to the general terrain, as well as to the local conditions, particularly as it was written soon after the storm and probably before all possible data could be obtained and digested. The records of the U. S. Engineer Office at Fort Sam Houston agree substantially with those presented by the author and only a few slight differences are worthy of mention.

Some slight differences in data were observed regarding the flow in the various streams, which are submitted herewith, as they show a slightly more constant maximum discharge per square mile. The maximum discharge from the Olmos, as computed by the office of the Engineer, Eighth Corps Area, was 25 000 sec-ft., which would give an estimated flow of this basin of about 930 sec-ft. per sq. mile. For Apache Creek, an estimate fixed the maximum discharge at 22 560, or 947 sec-ft. per sq. mile. On the Martinez-Alazan, the maximum flow estimated was 24 000 sec-ft., or 1 223 per sq. mile.

The flood was the result of a rain storm, of which the zone of greatest precipitation lay easterly and westerly across the head-waters of these streams. In San Antonio, the flood peaks of the Alazan and Apache Creeks arrived at different times. The peaks of both had passed before the slower gathering flood from the San Antonio River arrived. Had a combination of circumstances made the crests of the various creeks arrive simultaneously, the damage to the lower part of the city undoubtedly would have been much greater. As it was, the river, in the southernmost part of the city, overflowed its banks only slightly.

Since his paper was written, the committee of engineers referred to by Mr. Bartlett, has recommended methods to prevent a future recurrence of these floods. This plan provides that the channels of the San Pedro, Alazan, and Apache Creeks be widened, deepened, and straightened, that the grades along the banks generally be raised, and that a strip of varying width on these streams be reserved through the town. This part of the city is not nearly

* Col., Corps of Engrs., U. S. A., Fort Sam Houston, Tex.

as thickly settled and the land is less valuable than that in the valley of the San Antonio.

On the San Antonio, where the land is too valuable to allow purchase of a strip wide enough to carry the full flood flow, the Committee recommends a straightening of the river by the elimination of several large bends within the city and a slight deepening and widening of the channel. This channel now has a capacity of approximately 6 000 sec-ft. in its improved parts, and will have its capacity increased to 15 000 sec-ft. In addition, the Committee recommends constructing a concrete retention dam to form a dry reservoir at a point near the mouth of the Olmos and about 2 000 ft. north of the northern boundary of the city, where borings indicate a good foundation. This dam is to be provided with permanent openings to allow the discharge of 6 000 sec-ft., retaining all peak water in excess of that quantity until the channel can carry it. The estimated cost of this construction is $5 500 000.

C. E. ELLSWORTH,* ASSOC. M. AM. SOC. C. E. (by letter).—The author is to be commended for his initiative and promptness in collecting much valuable data regarding the San Antonio flood and for his service to the Profession in making such data available.

The writer has prepared this discussion for two purposes:

1.—To make available in printed form, in advance of official publication, the records of stage and discharge of San Antonio River, that are on file in the office of the U. S. Geological Survey and the State Board of Water Engineers at Austin, Tex.

2.—To prevent the impression that a reasonably accurate rating and determination of discharge during the flood could not be made, because the water-stage register, referred to by the author, was located at the South Alamo Street Bridge, which failed.

In discussing the accuracy with which the discharge could be determined, the writer is unable to recall the exact statements which he made to the author at different times, immediately after the flood, but he was then of the opinion and probably conveyed the idea that the rating was less accurate than the final analysis indicates.

Like practically all such determinations during great floods, the calculations of maximum discharge and run-off are liable to considerable error. The writer believes, however, that the accuracy with which this flood has been measured is relatively high, because a practically complete graph record of stage was obtained and because the stretch of channel a short distance down stream from the gauge was relatively favorable for the determination of peak discharge by the slope method. Sufficient current-meter measurements of discharge are available for the low and the medium stages, so that no gross errors are possible in the rating. (See Table 1.)

The author has stated that:

"It is unfortunate that the water-stage register of the Geological Survey was located at the South Alamo Street concrete bridge which failed. Although the gauge itself was undamaged and recorded the levels, except for 3 hours

* Dist. Engr., U. S. Geological Survey, Austin, Tex.

at the crest, the failure of the bridge interfered with the channel, so that no accurate rating curve can be established for the flood conditions."

TABLE 1.—LIST OF DISCHARGE MEASUREMENTS OF SAN ANTONIO RIVER, AT SAN ANTONIO, TEX.*

Number of measurement.	Date.	Gauge height, in feet.	Discharge, in second-feet.	Method.	Location.
81	March 11, 1921	2.51	391	Current-meter	At gauge
87	Sept. 8, "	1.38	76	"	"
88	Sept. 9, "	3.31	622	"	"
89	Sept. 10, " †	20.14	15 300	Slope	2 000 ft. below gauge
90	Sept. 10, "	8.94	2 200	Current-meter	Nueva Street Bridge, 1.3 miles above gauge.
91	Sept. 10, "	5.57	866	"	Railroad bridge, 400 ft. above gauge
92	Sept. 21, "	3.13	153	"	At gauge
93	Oct. 4, "	2.90	117	"	"

*Numerous discharge measurements, not listed, have been made at stages less than 2.00 ft.
†Measurements of cross-section and slope were made on September 15th to 17th, 1921.

The water-stage register was installed in April, 1920, by the Engineering Department of the City of San Antonio, according to a plan prepared by the Water Resources Branch of the U. S. Geological Survey which maintains a District Office at Austin in co-operation with the State Board of Water Engineers. The site, at the down-stream side of the right abutment of the South Alamo Street Bridge (Fig. 5), was selected by Hans Helland, M. Am. Soc. C. E., then City Engineer, and the writer, after a thorough examination of the course of the river through the city and a careful consideration of all conditions that might affect the accuracy of gauge records and the determination of discharge. The writer is now more firmly convinced than ever that a better record of the flood could not have been obtained at any other location, except, possibly, farther down stream, in the vicinity of the section used for the determination of discharge by the slope method. The use of that section, however, is dangerous owing to the possibility of back-water from San Pedro Creek and from débris that is likely to collect at the crossing of the Missouri, Kansas and Texas Railroad Bridge. A study of the overflowed area and of the condition of the channel, due to obstructions caused by débris collected at bridge piers and other constricted sections, shows that the relation between stage and discharge at any section above the South Alamo Street Bridge would have been decidedly uncertain at any time during the flood, and that the flow of water below the gauge was relatively unobstructed and permanent. Even after the bridge had failed and partly collapsed, the channel capacity was not reduced as much as it was at many other bridges which did not fail, but at which greater quantities of débris were collected. Practically, the only effect the failure of the bridge had on the rating was caused by a few small blocks of concrete, which broke loose and lodged in the channel below the gauge. That effect has been determined quite definitely by comparison of measurements made before and after the flood, at relatively low stages. (See Fig. 9.) The difference in discharge between the curves, considered as a per-

centage of total discharge, would be less for higher stages and would be negligible at the crest; therefore, in the absence of definite information as to whether the blocks of concrete found in the channel after the flood were dropped there before or after the time of the maximum stage, both curves have been drawn through Measurement No. 89, which represents the discharge at the maximum stage.

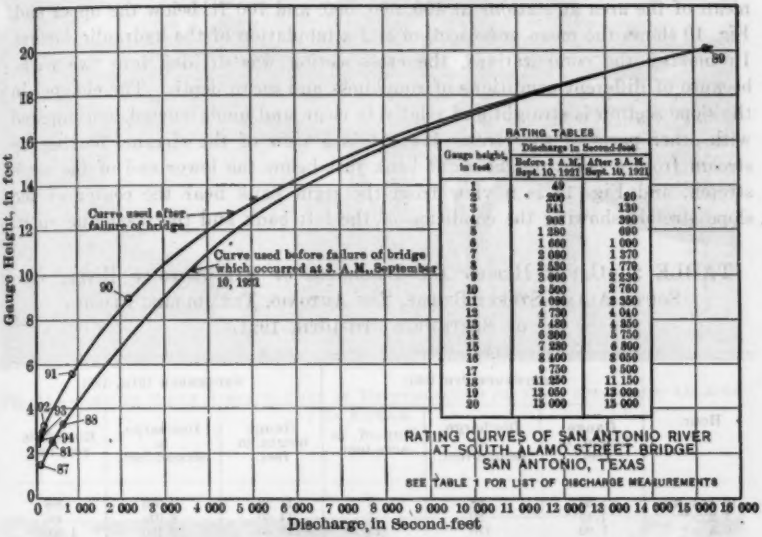

FIG. 9.

The discharge at the maximum stage was determined by the slope method, by using Kutter's formula. The high-water slope had been well marked by floating oil. A stretch of straight channel, 800 ft. long, about 2 000 ft. down stream from the gauge, was selected. The center of this stretch is near the intersection of Temple Street with the river. Cross-sections were taken

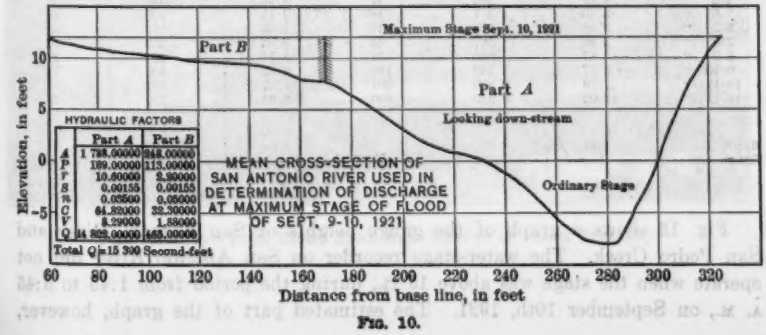

FIG. 10.

every 100 ft., and the slope was carefully measured on both banks. The slope on the left bank, for the upper 375 ft. and the lower 50 ft. of the stretch, was irregular and differed in form from that on the right bank. The left bank which is bordered by buildings and other obstructions, was overflowed, but the right bank which is high, was not overflowed. The difference was probably due to these facts. For the intervening 375 ft., the slopes on the two banks were in close agreement, and the mean slope was used, the area being the mean of the area at stations at 400, 500, 600, and 700 ft. below the upper end. Fig. 10 shows the mean cross-section and a tabulation of the hydraulic factors. In making the computations, the cross-section was divided into two parts, because of different conditions of roughness and mean depth. The channel in the slope section is straight and relatively clean and unobstructed, as compared with other parts of the river. Fig. 11 is a view of the channel looking up stream from a point on the right bank just below the lower end of the slope stretch, and Fig. 12 is a view from the right bank near the center of the slope stretch, showing the condition of the left bank and the flood line on it.

TABLE 2.—GAUGE HEIGHT AND DISCHARGE OF SAN ANTONIO RIVER, AT SOUTH ALAMO STREET BRIDGE, SAN ANTONIO, TEX., DURING FLOOD OF SEPTEMBER 9TH-10TH, 1921.

Hour.	SEPTEMBER 9TH 1921:			SEPTEMBER 10TH, 1921:

Fig. 13 shows a graph of the gauge heights of San Antonio River and San Pedro Creek. The water-stage recorder on San Antonio River did not operate when the stage was above 15 ft., during the period from 1:45 to 5:45 A. M., on September 10th, 1921. The estimated part of the graph, however,

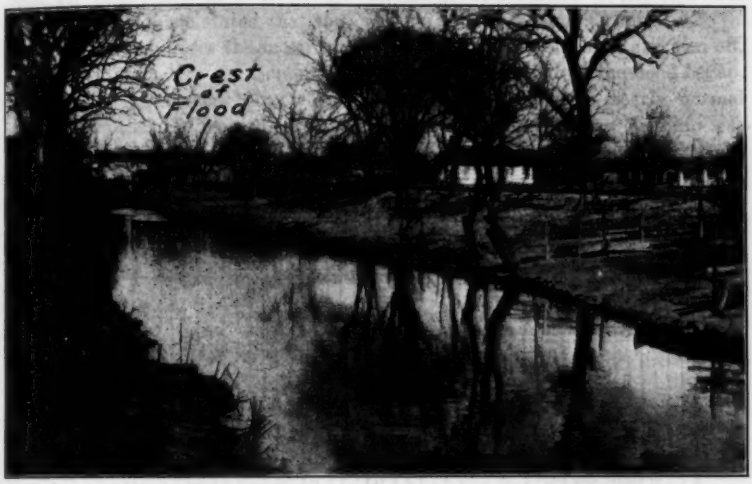

FIG. 11.—VIEW OF SLOPE STRETCH USED IN DETERMINATION OF PEAK DISCHARGE, LOOKING UP STREAM.

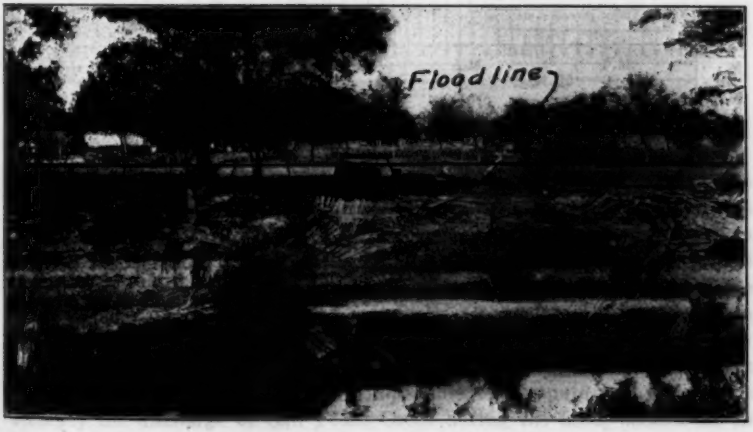

FIG. 12.—VIEW FROM RIGHT BANK NEAR CENTER OF SLOPE STRETCH.

can not be greatly in error, because the maximum height of 20.14 ft. is clearly marked in the gauge house, and the time it occurred has been quite definitely established as 3 A. M., by statements of residents living near the gauge, who also have stated that the crest stage lasted about 30 min.

Table 2 which gives the mean hourly gauge height, discharge, and run-off, in acre-feet, from 12 A. M., September 9th, several hours before the flood began, to 12 P. M., September 10th, when the river had receded to nearly normal stage, shows that the most disastrous flood in the history of San Antonio was caused by less than 8 000 acre-ft. of water.

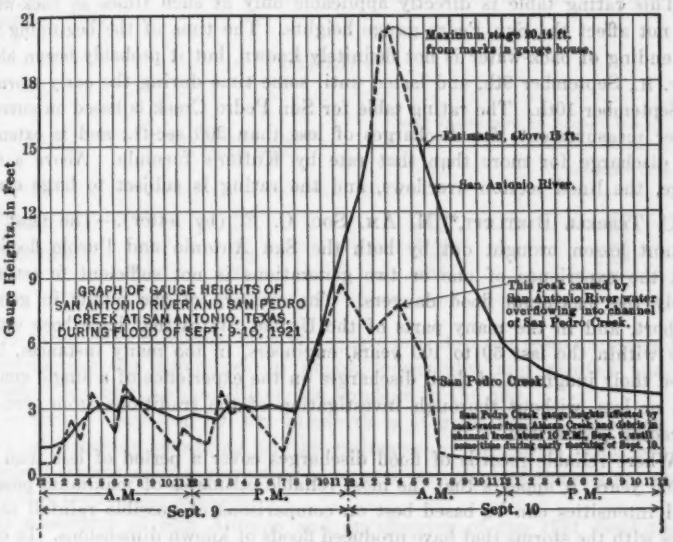

FIG. 13.

The water-stage register, on San Pedro Creek, is at the lower end of the covered part of the concrete-lined channel that extends from Durant Street to Arsenal Street. The graph of the gauge heights of San Pedro Creek is shown in connection with those of the San Antonio River, because of its possible value in determining the volume of water that passed over the divide from San Antonio River into the San Pedro Channel. The rise, shown in Fig. 13 as coming from San Antonio River, obviously did not come from any other source, as the flood-water from the San Pedro Basin had passed the gauge several hours earlier. It is impossible to compute with reasonable accuracy the discharge of San Pedro Creek during the flood, because of an indeterminate volume of back-water from Alazan Creek. The following rating table for the San Pedro gauge is submitted for the benefit of any one who may be sufficiently interested to attempt to compute the volume of water that passed from the San Antonio River Basin down the San Pedro Channel:

Gauge height, in feet.	Discharge, in second-feet.	Gauge height, in feet.	Discharge, in second-feet.
0.5	8	4.5	610
1.0	38	5.0	728
1.5	80	5.5	848
2.0	137	6.0	970
2.5	210	6.5	1 095
3.0	297	7.0	1 220
3.5	394	7.5	1 345
4.0	500	8.0	1 470

This rating table is directly applicable only at such times as back-water did not affect the San Pedro gauge heights. The time of the beginning and the ending of back-water is not definitely known, but it probably began about 10 P. M., September 9th, and lasted until some time during the early morning of September 10th. The rating table for San Pedro Creek is based on current-meter measurements for discharges of less than 200 sec-ft., and is extended for discharge for more than that rate by Kutter's formula. Above a 6-ft. stage, the lined section overflows, and the rating is subject to large errors.

C. TERRELL BARTLETT,* M. AM. SOC. C. E. (by letter).—The most important lesson brought out by both the San Antonio and Pueblo floods is that the experience of one or two generations is not sufficient to estimate safely the maximum flood dangers. The memory of the public in general is short, and in the many parts of the United States that have been settled only within the last 50 to 100 years, engineers, in too many instances, have based their judgment of flood discharges on the experience of a single generation or less, without thorough investigation of the traditions from even the preceding generation.

Where reliable records of flood discharges cover a period of less than 100 to 200 years, it appears that the most reliable estimates of maximum possible flood intensities can be based best on comparisons of possible rainfall intensities with the storms that have produced floods of known dimensions. In cases where such studies indicate flood magnitudes far in excess of the experience of one or two generations, and in cases where absolute safety is requisite, the engineer must have the courage to stand by his convictions in providing for the unprecedented. Had it not been for the old Spanish record of 1819, it is doubtful whether any engineer would have estimated a flood discharge more than double the greatest otherwise known at San Antonio.

Mr. Hazen's faith in the law of frequencies is amply supported by the record of that San Antonio flood. Except for this fragmentary Spanish record of more than a century ago, the 1921 flood might well have been regarded an anomaly, upsetting all theories of probability. However, it is found, as stated by Mr. Sherman, that the estimated flood of 100-year frequency, as determined from rain-storm intensities, is closely substantiated by two floods 102 years apart.

Another clue to possible flood stages is in the geological structure of a stream valley. Where there is a well-defined flood-plain structure, an estimated maximum flood discharge that does not correspond with a flooding of such

* Cons. Engr. (Bartlett and Ranney, Inc.), San Antonio, Tex.

valley, may well be questioned. An instance of this kind is in that part of the Rio Grande Valley in Southern New Mexico, known as the Mesilla Valley, where there has been no overflow of the entire flood-plain in historic times, but where Indian tradition tells of destructive floods. Fortunately, this valley is now protected by the Elephant Butte Dam.

With reference to the question of the discharge rates of the various streams at San Antonio, raised by Col. Jadwin, all the estimates are based on measurements of slopes and cross-sectional areas made after the flood, and no great accuracy can be expected. On reviewing the various estimates of flood discharge, the writer is of opinion that the values given in Table 3, may be finally recorded as the most probable crest discharge rates of the floods of September, 1921.

TABLE 3.

Stream.	Area of water-shed, in square miles.	Crest Discharge, in Second-Feet.	
		Total.	Per square mile.
Olmos	32.4	31 000	926
San Antonio	41	23 700	578
" "	45	16 000	356
Alazan-Martinez	16.9	28 000	1 656
Apache	22	19 000	864

The variation in discharge rates per square mile does not seem unreasonable, on considering the differences in slopes, topography, and rainfall and, in the case of the San Antonio River, the pondage in the city.

The timely discussion by Mr. Ellsworth is of great value in showing the degree of accuracy obtaining in the estimates of discharge made by the Geological Survey and in correcting a general statement of the writer, which might have been misunderstood.

As a resident of San Antonio and an observer of the 1921 flood there, the writer is impressed with the importance of the human or social aspects, as contrasted with purely economic considerations, in determining the extent and character of flood-prevention works. In cases where possible loss of life is a factor and where there may be many instances of ruinous individual losses, rather than a measured financial loss distributed on a whole community, the expenditures for preventing floods may justifiably exceed the amount computed by capitalizing the probable average annual flood losses.

Paper No. 1486

ODORS AND THEIR TRAVEL HABITS*

By Louis L. Tribus,† M. Am. Soc. C. E.

With Discussion by Messrs. Paul Hansen, George C. Whipple, Stephen DeM. Gage, I. S. Osborn, Rudolph Hering, Olin H. Landreth, Andrew J. Provost, Jr., Robert Spurr Weston, Alexander Potter, Caleb Mills Saville, George A. Soper, and Louis L. Tribus.

Synopsis.

A famous educator on being asked to explain the term "synopsis" replied by saying that it was an "epitomized exegesis". It is difficult to present a synopsis of this paper, for it is more a rambling collection of notes about "smells", with some incidents illustrating their intensity, prevalence, persistence and movements, than a logical engineering presentation of a definite subject, with conclusions, as a suggested guide to follow. In fact, definiteness as to smells is impossible, even as to any standard of describing them, and the paper makes a point of that fact.

The tolerance of odors given off by essential industries, if due care is taken to reduce offense to the minimum, is considered, the effect of odors upon persons of different susceptibilities is discussed, and the fact that certain races accept as pleasing those odors which produce even disgust in others is noted. Some notes are given in regard to difference of behavior during daylight and night, particularly the curing effect of direct sunlight.

Observed distances of travel of odors are given in numerous instances, and various cases from litigation are reviewed, giving opinions of unnamed experts as to their views on distances to which odors travel, and the atmospheric conditions under which they become specifically obnoxious.

In general, the types of odors reviewed are those from garbage treatment and sewage disposal works, with some comments on the production of offensive gases in the preparation of food products, ore and oil refining, etc.

* Presented at the meeting of November 16th, 1921.

† Cons. Engr. (Tribus and Massa), New York City.

The writer's conclusions are that many engineers should give items from their own experiences, and thus provide a reservoir of information that might be helpful in settling various disagreements and even litigation; that chemists might devote more attention to counteractive work; and that some consideration might be given to amendments to public health laws to make possible the stopping of prospective nuisances without having to wait for their actual development before effective action can be taken.

The dweller in the country can generally count on fairly pure air, unrestricted light, good water, and, with a little intelligent care, suitable drainage and sanitary disposal of wastes. The city or townsman exchanges his freedom from drudgery for a dependence on united efforts to secure the necessities of community life, and encounters thereby many experiences in a lifetime where actual nuisance prevails, detrimental to comfort, if not perchance to health.

Odors (which, when offensive, are usually called "smells") are given off in the conversion of raw materials into food, oils, many metals, gas, and a countless list of articles for human use; and, again, through their passage back from such use either to their original or to transformed components.

Some of the objections to such conditions are sentimental rather than otherwise, but the result is the same—vigorous objection giving rise to talk, litigation, and sometimes actual violence.

The personal equation is a strong factor in considering questions of nuisances and their elimination, for there may well be a tolerance bred by acquaintance, or so overwhelming a need for the product, that humanity accepts the conditions without rebellion.

Only recently some of the older children and adults on Barren Island, Brooklyn, N. Y., were asked "What do you most desire?" The response was unequivocal, "Give us back the operation of the garbage plant." With all its atrocious features, it meant employment, money, and upkeep of their homes.

Garbage and Sewage Phases Considered.

This paper presents items chiefly from the garbage and sewage phases of the question—for they have come more directly into the writer's purview—and the traveling qualities of odors therefrom, rather than the methods of production.

A point of interest raised, about which there might be much discussion, is the advisability of making lawful the veto power by Health Commissions or Courts on projects that practically promise the creation of nuisance, rather than waiting for full construction and actual accomplishment.

As far as "smells" go, there is a wider field for study in counteraction than prevention, for the latter is costly and frequently litigious.

It may be venturesome for an engineer having only an elementary knowledge of the chemical and microscopic constituency of gases and their structure to attempt any characterization of odors (or smells) and their habits of travel. However, having been called at times to make use of nasal, visual, and sometimes stomachic susceptibility where questions of nuisance from odors had

been raised, the presentation of some notes may be pardoned, in the hope that discussion may bring together more data, crystallization of facts, and agreement as to procedure for the benefit of community welfare.

Mathematical Measurement Impossible.

To begin with, from a mathematical viewpoint the case is hopeless. One cannot say that a particular odor, given off at a specific heat, meeting a certain open-air temperature, at a special barometric pressure and known degree of humidity, with a wind blowing just so many feet per second over a level plain, will be clearly noticeable at a computable distance from its source.

Therefore, why should any solution of the case be sought? Simply because odors do travel, and opinions are desired which may result very tangibly in settling litigation, where questions of damages and injury to health are at issue.

From an article in *The Lancet* are extracted the following passages:

"If more studied the sense of smell might have been cultivated * * * and the study of odors would have reached a higher plane, though it appears to us the classification of smells must always suffer from the absence of the mathematical analysis capable in optics and acoustics. As it is, in our struggle to describe a smell, we are confined to using such terms as 'peculiar, persistent, pleasing, disagreeable, sour, bad, musty, sickly and so forth'. Now these are all adjectives which give us little enlightenment * * * as compared with color and sound and light mathematical laws. * * * Perhaps sometime smells may be also arranged according to some scale."

The foregoing is quite true; probably six simultaneous observers of six odors, describing them independently, would use not the same six adjectives but at least twelve or fifteen. The real point of importance, however, is the distance that smells travel and their actual effect on human beings.

State Laws Control Nuisances.

State laws usually empower boards of health to control nuisances, nuisances being generally described as "such conditions as offend humanity, either personally or through injury to property, or that may be considered as even detrimental to public health."

Decision is largely dependent on such individual cases as may be in point, and the enforcement of restrictions of noisome operations is dependent largely on the locality and the importance to the public of the operation itself. Some trades are essential, yet offensive; they may be tolerated in one place and debarred in another, yet with equal justice.

The second factor of importance brings in the human equation. Some individuals possess a keen sense of smell without effect other than objection to the disagreeable; some are violently affected; others are less keenly, although nervously, affected, and in the end seriously so. The symptoms in most cases are usually loss of appetite, headache, or even nausea.

Some races may not only tolerate but positively enjoy an odor that produces rank disgust in others. All know also that sometimes a whiff of an odor is offensive, while a well saturated atmosphere brings toleration; at other

times, and more usually, the reverse follows, consequently, no definite rule could be of universal application.

The Seal and Cod Liver Oil Works of Newfoundland, to the casual visitor, are offensive in the extreme, yet those living near-by become accustomed to the odors, which are typically rancid and more than suggest putrefaction. Fortunately, they do not carry far from the plants, or else they become so quickly mixed with the strong ocean air as soon to pass from recognition. They are essential local industries, and hence they are tolerated even if perchance disliked.

Control by Anticipation.

As yet the law does not permit control by anticipation; actual nuisance must be first produced; then, however, action may be swift and effective. Would it not be wiser, under well safeguarded acts, to permit legal review by boards of health before consent is granted to invest capital, where noisome odors might be anticipated? Of course, there are injunction proceedings open to taxpayers, but if State or municipal consent was first required, much litigation might be saved in later complications.

However, legal consents or litigation throw no light on odors traveling, the present point of special interest.

Special Cases Cited.

The writer recalls two cases during his boyhood, one a tomato catsup factory which kept in the open yard several tanks of pulp, just how far the pulp was advanced in putrefaction and how much was bottled for sale not being of present importance, and the fact is that, although very offensive within 100 ft., the odor could rarely be noted farther away. Operations were closed by order of the health authorities, but on grounds of unsuitable materials rather than general nuisance.

The other case concerned a cream of tartar establishment, where apparently due care was observed in manufacture, yet the vile odors traveled with almost increasingly disagreeable qualities to a distance of at least a mile under almost any atmospheric condition. In this case, a shut-down was soon effected on the score of nuisance, though not necessarily directly injurious to public health. The plant was located at the edge of a populous community, and could not be considered an essential industry.

The garbage reduction works on Barren Island (within the Borough of Brooklyn, City of New York) were for years synonymous with stench. Fumes from the retorts and tankage driers passed off in part through the chimneys from which, according to wind and humidity, they traveled 5 or 6 miles, or more, before diffusion and chemical break-up relieved the offense.

These odors, while disagreeable, were not particularly nauseating to most people, and for many years legal actions to end them were not effective. Recently, however, a permanent injunction has been granted. Close to the plant, although intensified, the odors were scarcely more offensive than at considerable distances.

Experience at New Works on Lakes Island.

The great reduction plant, built in accordance with many advanced ideas, and located on Lakes Island to replace the Barren Island works, for the several months of operation prior to its being closed as a nuisance, gave off gases that persisted in nauseating quality and strength to points 8 and 9 miles away. Rather curiously, although twenty-four hour operations were maintained, these peripatetic smells became more offensive after sundown. Evidently, the sun's rays possessed a deodorizing power which was joyfully welcomed by the burdened population through those months of torment.

Years ago, it was discovered, practically by accident, that sunlight streaming into tanks holding tried out seal oil, while going through the curing process, killed in large measure the exceedingly vile odors of decomposition, and thus made life endurable for the workmen.

The odor problems of many cities, aside from offensive trades, are those from garbage works and sewage disposal systems. A great many reams of paper have been covered with lawyers' briefs and thousands of witnesses have been examined in trying to solve the difficulties due to noisome smells; individuals attacking communities and private corporations, and communities attacking each other.

New York Case Against Bayonne, N. J.

A long drawn-out action was that of New York State *vs.* New Jersey, trying to enjoin the passing of corrosive gases and offensive odors from certain great manufacturing plants in Bayonne, N. J. Although no summary closure was effected, a very great amelioration was secured. A rather noteworthy step was taken by some of the defendants in gathering the worst gases into two great chimneys, and passing them into the air at a height of 360 ft. or more above ground. Although the eye can see the output drifting for several miles, diffusion and perhaps transformation largely occurs before the odorous gases descend to ground level again, unless a strong wind blows them earthward to produce their old-time results of throat and nose irritation (fumes from copper smelting predominate). Such fumes quickly kill vegetation.

Another bitterly resented crop of fumes came from great manufacturing establishments, again along the New Jersey shore, at Edgewater. In spite of the mile of Hudson River water between the shores of what is virtually a great canyon formed by the high banks, residents along Riverside Drive, New York City, and other neighboring streets, were driven almost frantic at times by the peculiar and irritating gases given off in the preparation of certain foods, chemical, and other commercial products.

Here, again, litigation and pressure have forced great changes for the better, but the point of present importance is not the peculiarities of litigation or the fact that usually such pressure brings some relief, but rather that odors do travel. Of still greater importance is the fact that such odors can usually be anticipated and controlled.

Gas Manufacture Now Inoffensive.

The earlier manufacture of illuminating gas was attended by odors from the wastage of the first output of the retorts and from the usually open tanks

of coal-tar and other by-products. Unless disseminated by strong winds these odors did not, as a rule, make themselves known at great distances, rarely more than ½ mile, but much litigation ensued nevertheless, particularly in Great Britain. At present, with the use of oil so largely replacing coal in illuminating gas manufacture, there is less of the waste from retorts, and the by-products, having commercial value, are conserved at once for sale. As a consequence, gas-making has nearly left the ranks of offensive industrialism, barring occasional accidents or carelessness.

In considering odors which give offense to communities, those from fuel consumption are largely ignored, for when serious in nature, it is more because of mixture with unconsumed carbon in the smoke, rather than the irritating or noisome constituents themselves; furthermore, dwellers in cities are so thoroughly saturated with ordinary coal gases as to have largely passed the stage of noticing them, unless they are present in great excess.

Soot as a Nuisance.

The soot elements have been productive of many a strenuous fight, and will still continue to do so until that day comes when, with power plants at the coal mines, electricity will be developed to do much more of its cleanly work in the cities, with the tremendous saving in labor, space, wastes, etc. The imagination could well run riot over the practical advantages of electric power, and with only a trifling betterment in mechanical conditions, the ultimate economies also. Of course, water power converted to electricity will produce the same result.

A public commission in Idaho, not long ago, issued its opinion, after obtaining much testimony, that electricity cannot take the place of the direct use of coal for heating; another body in Ontario came to a somewhat similar conclusion. Positiveness, however, is dangerous and the "cannot" of to-day becomes the "accomplishment" of to-morrow.

Odors Carried Long Distances.

Long before land can be seen from the ship, the peculiar and rather pungent odors of tropical vegetation in the West Indies can be discerned, indicating their travel of 25 or 30 miles at least. The ocean waters themselves may be somewhat responsible, due to stream flow and land washings, but it is atmospheric carriage in largest measure.

That leads to another phase of the subject, where possible absorption of gases by water, with movement to new scenes of activity before final transformation or diffusion of obnoxious elements may tend to a later separation, again of gaseous products, and to the extent of causing a transplaced nuisance. This has been often noted in sewage cases, where volatile elements from treated sewage effluents seem to have been carried in actively flowing streams for considerable distances.

In such cases, however, unless atmospheric conditions are very favorable, these finally liberated gases do not usually travel far from the stream itself. Even in the case of the Lower Passaic River, Gowanus Creek, and formerly

the Chicago River, the well-known trio of unenviable waters charged to practical saturation with sewage, the odors were not noticeable usually for more than a few blocks away from their banks.

From a recent report of the Albany Sewage Disposal Plant, the following statement is quoted:

"There is practically no nuisance caused by odor from the plant, as it has never been discernible for a greater distance than 300 yd., and then only on muggy summer nights."

Odors from Garbage Treatment and Sewage Disposal.

Returning, however, to the fields in which many communities have a common interest in either providing against prospective nuisances or in curing them when created, namely, garbage transportation and treatment and sewage disposal, a brief word on processes may not be amiss.

In the treatment of garbage, aside from field spreading, three distinct methods are in vogue, each with its strong advocates, and each, of course, with its various modifications:

(*a*).—High temperature incineration (1 300 to 2 200° Fahr.) where, under proper operation, no offensive odors pass from the plant except that a slight "caramel" aroma may at times be noted in the fleecy, whitish smoke that comes from the chimney, but is scarcely objectionable except to the ultra-sensitive. We do not speak of esthetic objections, but rather of sensatory causes.

(*b*).—Reduction by cooking, according to one or another of several processes. To date, except from perhaps very small scale operations, odors are given off from all practicable plants, having quite distinctive characteristics of aroma, persistence in staying qualities, and decided diligence in travel. These have already been referred to in the cases of the Barren Island and Lakes Island plants, of different types; the same conditions prevail at Boston and Cleveland, and perhaps not quite so noticeably, yet actually, at Columbus and Chicago. In the latter case, the situation is such that other kinds of odor-producing establishments are near-by, so that any one is less conspicuous.

(*c*).—Transformation by hog feeding. This became during the World War a popular and intensive process and a profitable one, but less so now that the price of pork has dropped back nearly to old-times rates. Properly managed, it may not contribute largely to community smells, but in olden days the reputation of hog farms was not enviable, their sweetish and swill odors being distinctly noticeable at considerable distances.

The Lakes Island Case in New York.

The Lakes Island (New York City) reduction case, being quite recent and very hotly contested, might be reviewed at some length, to indicate the lines of thought developed and opinions brought out. It progressed in three stages, as follows:

First.—The objection of residents of the Borough of Richmond, New York City, to having erected within its confines a plant planned to reduce

about 2 000 tons or more of garbage per day produced by three of the other Boroughs, entailing also the transportation of such garbage on scows closely paralleling for 5 miles the course of the Municipal Ferry which carries about 45 000 passengers daily, and passing along and within a few hundred feet of about 10 miles of Staten Island's water-front.

The State Commissioner of Health held a long series of hearings, calling to sit with him a Professor of Sanitary Engineering of Harvard University and a Deputy State Attorney General. The case was conducted by the District Attorney of Richmond County for the protestants; by an Assistant Corporation Counsel of New York City (defending the contract); and by counsel for the Metropolitan By-Products Company, the prospective erectors and operators of the plant. A great deal of testimony was taken, the hearings extending over many weeks, resulting in a report to the Governor that a nuisance would probably develop, but that until such nuisance actually occurred, the State law would not permit action. The Governor instructed the Commissioner of Health to keep close watch, and directed the District Attorney to report also to him at the first indication of trouble, so that he might take summary steps for abatement.

Second.—The residents of Richmond were not satisfied, even though having full confidence in executive intent, and, consequently, a Special Grand Jury took cognizance of the case and through the District Attorney and special witnesses, became advised of many facts, but again found that limitations of law prevented effective action. The construction of the plant had progressed, however, nearer to completion and early operations fully verified anticipation, that while perhaps it was possible to operate without offense, it was not practicable so to do. A presentment but no indictment followed.

Third.—The New York City Health Commissioner took a hand, operations on nearly full scale having been undertaken, and after hearing much testimony, expert and lay, very quickly decided that the nuisance was actual, intolerable, and unjustifiable, and forthwith forbade further operations. Combined with this official "order" came bankruptcy of the Company, and the residents were relieved of their troubles.

The odors were of nauseating quality and were seriously offensive at distances of at least eight miles from the plant. The discriminating nose could detect three characteristics in the stench: that of caramel or burning vegetable matter, semi-rancid decomposing swill (combined vegetable and animal elements), and of the solvent (a chemical midway between gasoline and kerosene).

These odors would settle in topographic and atmospheric pockets, and treated the public to many surprises as to their lasting qualities and intensity. The effect on different systems was quite diverse, producing severe headaches in many, nausea in others, lassitude in some, and generally violent wrath in all.

Varying Opinions of Experts.

In the two earlier proceedings the opinions of experts varied widely, several testifying for the Company. The City took the position that odors of rotting garbage, conveyed on open scows, if covered with tarpaulins, could

not escape and would not be noticeable more than about 100 ft. away, at worst. Others stated that from the plant built and operated as promised there could be no escape of gases to annoy even visitors to the property.

Theoretically, the last condition should have been true, except for the unloading of the partly decomposed materials. Practically, of course, no such operations would be carried on as they should be, and hence the conditions that actually developed should have been anticipated, in part at least.

There was much testimony offered as to the prospective and real qualities of the gases to be produced, and as to those actually emanating from the plant. This testimony tended, in weight of opinion, to support the claim of their being detrimental to health, even if not actually or violently poisonous.

There could be no divergence of unbiased opinion as to their injurious effect on real estate values, and as the loaded scows in service were not well covered, all theories as to their agreeable nature were "knocked endwise."

Details of Methods.

As to process, the following may be helpful to an understanding of the situation. The scows holding from 300 to 500 tons of garbage from 2 to many days old were towed from the Bronx, Manhattan, and Brooklyn to and alongside an open wharf at Lakes Island along the west coast of Staten Island, Borough of Richmond, City of New York. Grab buckets lifted the mixture to hoppers from which belt conveyors carried it to the double kettles holding 5 to 6 tons each. Live steam, introduced into the space between the inner and outer kettles, cooked and vaporized the constantly stirred mass. As the watery vapors passed off through a check-valved steam pipe system, solvent was pumped in to digest the grease. After 8 to 12 hours treatment, the dissolved grease was drawn off for settling and barreling. The vapors were supposed to be condensed for recovery of the surplus solvent, and the fairly dry tankage was conveyed to the storehouse, first being roughly screened, to take out such bones and rags as had escaped the pickers while the raw goods were on the first belt conveyors. Cans, glass, table silver, paper, and a multitude of articles were taken out by the human pickers in that stage of the work.

All processes where heat would develop odor were supposed to be closed, but carelessness, leaks, and failure in some features of the plant, permitted the escape of smells that, as a stench, brought catastrophe.

Monticello Sewerage System.

Another recent instance of litigation over odors has grown out of the operation of the Monticello sewerage system. About ten years ago, that village called on the writer's firm to modify, if necessary, and complete the system that had been well started, the designing and supervising engineer of which had died.

As completed, the disposal works occupied a somewhat swampy area of rather tight soil and consisted of three covered sedimentation tanks, four open stone contact beds, and two large open under-drained sand filtration

areas, the processes being successive, and operation alternating. The effluent from the under-drains, and from the sludge bed (used about once a year) passed into a brook which a few hundred feet away united with another stream that carried the village street drainage, and a smaller one that also first passed partly through the village.

Tannery sewage, after going through its own detention septic tanks, entered the sewerage system, but apparently did not materially interfere with bacterial action in the disposal works, although it added at times elements of color from waste dyes.

At a distance of ½ mile from the works, the combined streams crossed a main highway, near which was a summer boarding house. The owner brought suit for losses of income, charging that odors from the disposal works had driven away the boarders.

The normal effluent from the plant was clear, practically colorless, and almost odorless. The odor could scarcely be noted 50 ft. away, and along the flow line of the brook soon became so mingled with the swamp smell as to be indistinguishable. At times, however, some carelessness of operation or accident, or flood conditions, carried an overflow of liquid from the sand beds into the brook, this liquid being the result of two processes of bacterial break-down. Also, under certain atmospheric conditions, while the twice treated sewage was standing on the sand beds, slowly percolating to the under-drain, odors rose and sluggishly moved over the nearly level valley, then combining with the plaintiff's own cattle and hog yard smells and the natural swamp vapors, produced an unpleasant effect.

A great deal of testimony was taken in the many days given to the trial, tending to substantiate the claim that sewage odors did at times travel the ½ mile or more. Whether such fact could carry financial damages was solely within the province of the Court to say. It was clearly brought out and acknowledged that the plant itself was suitable, and properly installed.

The consensus of testimony was to the effect that atmospheric conditions as to humidity or dryness largely affected the lasting and persistent nature of the odors, and that light winds would carry them to considerable distances, while heavy winds would cause rapid diffusion and soon put them "out of business."

The Court rendered a rather unique decision, awarding $1 200 damages in the $25 000 claims, divided $400 payable by the village, $400 by unknown offenders, and $400 by the plaintiff himself as a contributor to the trouble. The village is also directed to enlarge its plant, so as to care more adequately for the maximum sewage load.

General Testimony on Odors.

Writers have in general expressed themselves rather conservatively, as a rule, when treating the subject of odors, for except when personal experience is available, little that is conclusive has been brought out.

One well known treatise on sewage states that "odors of aerobic treatment are less offensive than from anaerobic." In other words, open-air oxidation

gives off less putrid gases than closed bacterial methods. In another passage, the same treatise states "fresh sewage on trickling filters is not noticeable over 100 yards away * * *, from septic tanks some one-half mile." Another writer states:

"The odors which arise from decomposing sewage do not cause typhoid fever, or smallpox, or scarlet fever, or any other contagious disease. They may, and often do, reduce the comfort and happiness and, consequently, in a sense, the health of the people subject to them, but it cannot be maintained that they cause serious sickness."

From the testimony of experts in the Lakes Island case, the following brief sentences are quoted:

"Odors travel greatly under light air and high humidity."
"Garbage scow smells are noticeable from one-third to one-half mile."
"Odors travel 3 to 5 miles, increasing with quantity, * * * night travel is more offensive than day."
"Odors carry, say, three miles."
"Odors not so offensive with high winds."
"Barren Island odors are from the drying plant."
"Garbage odors will travel long distances."
"Could not smell plant (garbage) over 500 ft."
"Odors would not carry far."

Two of the Southern States a few years ago fought out very conclusively the principle that people are entitled to fairly pure air, as well as pure water; in that case, the fact of the travel of odors to an offensive degree and unreasonable distance was well established.

Recent Developments.

The phase of the subject considered in this paper is more that of odors which are offensive to people, than gases which cause damage to property. The principle is becoming more and more firmly established that upon the party giving the cause of annoyance devolves the duty of relieving it. In matters of sewage outflow into, and water supply from, the same stream there is a duty charged on both interests, first, to mitigate offense, and, second, to prevent danger; the right of drainage is held to be practically equal to the right to a pure water supply, so that treatment works are required to be operated by both parties.

At one time there was a great hue and cry about slaughter-houses in cities, and the offensive smells that came from them and passed liberally through the neighboring community. Many actions were brought to close them, but as a rule the Courts determined that the service was needed by the public, and Boards of Health were instructed to keep very sharp supervision to prevent needless annoyance.

Later, as a greater demand has developed for cleanliness, slaughter-houses have gradually almost ceased to be offensive. Economic questions also came into the case, for what had once been wasted and allowed to rot and smell, until sporadic house-cleaning was indulged in, became of value as commercial by-products. Blood once passing into sewers goes into feed and fertilizers; hair, hide, bones, horns, etc., all have market uses, and the offal in some

measure finds a sale; even considerable imports are brought to the United States of the entrails of animals killed in Japan and China.

To attempt to analyze an odor is hopeless, although it is certainly some form of emanation that has motive power of its own, but when sufficiently diffused is broken up into elements that cease to have original "personality", yet as long as traces last some characteristics persist.

The writer has visited many garbage treatment works and has noticed the clinging nature of the odors, which have often been retained by the clothing 12 or 15 hours after leaving the plant, being more noticeable from reduction than from incineration works. This is not indicative so much of traveling capacity, as of the simpler or more homogeneous form of the smell atom; it therefore does suggest a persistent character, hence, the ability to make itself known at great distances from the source.

Experiments have been made as to the toxic effect of garbage odors, but the results are not conclusive enough to warrant much discussion.

In the manufacture of linoleum and oil cloths, various oils are used, which, in changing to fixed forms, give off smells that permeate the air for sometimes several square miles around the plant. The preparation of linseed oil also produces smells that carry considerable distances. In neither of these cases, however, is there a condition that seems to develop unhealthful reactions in humanity.

From the foregoing and similar facts it may be asked, "Should and can odors be classified by any scale of descriptive terms? Can odors be analyzed to discover the atoms that make them agreeable or offensive, and thus find what other atoms may be needed and used to neutralize their influence?"

A homely instance is the cooking of cabbage and its filling a house with the characteristic and not altogether agreeable smell; a little soda in the water in which the cabbage is cooked practically neutralizes the odor without injurious effect. Parasites are grown to kill off other species detrimental to crops. Antidotes for many things that cause trouble are used.

There are, of course, well known germicides, but these are of greater service in arresting or counteracting putrefaction, than in transforming the gases already developed, unless to mix with them and by combination change their identity.

The work to be done may lie more in the field of the chemist, but the causes of many odors occur in the field of the engineer, so that from his knowledge and experimentation also there may come a solution for many a community's fears and discomfort, and prevention of the development of many an actual annoyance.

DISCUSSION

PAUL HANSEN,* M. AM. SOC. C. E. (by letter).—The author deserves great credit for preparing a paper on the elusive subject of odors. As he has pointed out, it is a subject which is so difficult to treat in a tangible and scientific manner that engineers have hesitated to make it the subject of discussion before technical societies. It would seem, however, that a fuller discussion of the subject, on the part of engineers and chemists, might lead to more standardized, definite, and scientific means for measuring the quality, intensity, and carrying powers of odors, than are in use at the present time.

As the author invites experience from other engineers, it might not be inappropriate to refer to a report on odors from an oil refinery, recently prepared by the writer in collaboration with F. C. Dugan, Assoc. M. Am. Soc. C. E., Chief Engineer of the State Department of Health of Kentucky, and G. C. Smith, Professor of Engineering Chemistry at the University of Cincinnati. This investigation seemed to call for some general remarks on the subject of odors, which are quoted essentially as follows:

"The effect, psychology, and significance of odors constitute a rather confusing subject especially to the lay mind and frequently to the legal mind. A primitive sense of odor was apparently designed by Nature to (1) distinguish inedible from edible substances; (2) as a means of recognizing things and creatures; and (3), in some instances, as a warning against danger. Generally speaking, the disagreeable odors were those that indicated inedible substances and dangers. Persons instinctively associate disagreeable odors with dangers to health. So strong are these instinctive feelings that it is difficult to get people to believe that their health and lives are not in danger when in the presence of strange or disagreeable odors.

"As a matter of fact it can be very clearly demonstrated that odors in and of themselves are not dangerous to health, although they may indicate the presence of substances which if ingested or inhaled in concentrated form may have physiological results.

"In addition to natural odors, man's ingenuity has introduced many industrial processes that have odors. Most of these industrial odors when first encountered are regarded as disagreeable in varying degrees, certainly they are nearly always objected to when introduced near places of abode, not so much because they are hurtful, as because they prevent the free enjoyment of the atmosphere as Nature made it. Where industrial odors are accepted as a necessary evil, as is apt to be the case in a greater or lesser degree in all large cities and industrial communities, people become inured to the odors and either do not notice them or, in some instances, actually develop a liking for them. Grain mills, woolen mills, cotton mills, dye works, soap factories, slaughter-houses, sugar refineries, shoe factories, paper mills, rendering plants, tanneries, etc., all have characteristic odors, often mild, but sometimes rather strong, to which whole communities become accustomed and accept without complaint. There are certain industries, however, that produce odors so strong and so unpleasant that they are rarely permitted in residence communities. Among these 'offensive industries' are rendering plants, slaughter-houses, certain chemical processes, glue works, etc.; but even some of these odors are tolerated and accepted as a matter of course and as unavoidable. Perhaps the most notable example of this is the notorious stockyards' odor that frequently pervades the whole South Side of the City of Chicago, in

* Pearse, Greeley, and Hansen, Chicago, Ill.

which are included many fine residence districts. Apropos of this, the so-called inquiring reporter of the *Chicago Tribune* one day made inquiry at random of ten people on the South Side of Chicago regarding their attitude toward the odors from the stockyards. Only one stated that the odors were disagreeable, nine were indifferent to the odors, and one admitted that to him the odors were actually agreeable. In short, it is difficult to decide when an odor may be regarded as a public nuisance and when it may not be so regarded; the most one can say is that an odor is a nuisance if the public is not used to it and does not want it in the neighborhood. The same odor may not be a nuisance if the public is used to it or is willing to tolerate it for economic reasons or otherwise.

"Odors from oil refineries seem to fall in a middle class. Though some very sensitive persons may be nauseated by oily odors, the average person is not apt to describe them as distinctly disagreeable in concentrations in which they would ordinarily be found even in close proximity to a refinery. Nevertheless, the same average person would be very much averse to having these odors in and about his residence, much from the same point of view as people nowadays avoid living on streets extensively traveled by automobiles, or regard the odor from recently oiled streets as objectionable in their homes.

"In a broad way, the principle seems to be fairly well established in practice (and, apparently, in law as well), that essential industries even though odor-producing must be accorded an existence when once established. Recently, there has grown a tendency to regulate in advance the location of the more objectionable odor-producing industries by means of zoning ordinances or other regulatory devices, which accord suitable space to all industries, yet protect the property holders and stabilize real estate value.

"Some industries produce corrosive, blighting, and even dangerous gases, but these effects must be considered as distinct from odors, because certain of these gases have little if any odor. Zinc-refining and acid-making industries fall within this class. An oil refinery, however, could hardly be classed as objectionable on these grounds, as the concentration of escaping vapors is never so great as to affect vegetation or injure the respiratory tract. This is evidenced by the general freedom of employees of oil refineries from afflictions of the respiratory organs. Refinery vapors may contain certain substances that have a corrosive effect on metals and which may affect certain kinds of paints. These effects are most noticeable when the oil is rich in sulphur compounds. We are unable at the present time to make any more precise statement regarding the nature of these substances, but certain observed effects on paint, especially on the office building at the plant, indicate the presence of small quantities of some substance or substances capable of injuring lead paint. The testimony indicates that at rare intervals the paint on houses in the city is affected somewhat by these gases. Probably, most of the objectionable compounds come from the tail-house where unfinished oils are exposed and also from the agitator where gases containing sulphur compounds may escape in considerable volume."

In connection with the investigation and the report from which this quotation is taken, a limited number of observations were made on the effect of wind, temperature, and barometric condition on the dissemination of odors, in which the records of the United States Weather Bureau were found to be of great assistance and value. Owing to the limitations under which the investigation was made, however, these observations were not sufficiently long continued or sufficiently well carried out to warrant giving them any space in this discussion. However, they would suggest the possibility that it may be practicable to obtain a classification of odors according to some generally recognized standards. It may also be possible to trace the dissemination of

odors with parallel observations on meteorological and other conditions, so that it may be feasible after a sufficiently large mass of data has been accumulated to predict, under any given set of conditions, whether or not a sewage plant or a so-called offensive industry is likely to become the subject of complaint.

In regard to the author's remarks on the feasibility of preventing odors rather than having them abated, the writer wishes to emphasize the value of zoning ordinances in this connection. Zoning ordinances are now authorized in a number of States, and they constitute a most excellent means whereby odor-producing industries can be located in advance so that they will not prove to be a discomfort or injurious to property values.

GEORGE C. WHIPPLE,* M. AM. SOC. C. E.—The author has done well to bring to the attention of engineers this vexing question of odors and their travel habits. This question is inseparably connected with sewage disposal, stream pollution, garbage disposal, and many chemical industries. Odors that are offensive to human beings and travel over wide areas are public nuisances and come within the scope of police power, a power exercised in this case by State or local boards of health. There is hardly a question in public health administration which is more troublesome than this matter of odors. Several things contribute to make just decisions relating to odor nuisances difficult: The question of whether bad odors affect health; differences in people as to their sensibilities to odors, which are not only individual, but sometimes racial; physiological problems which are not well understood; the effects of temperature, moisture, and air movement, meteorological matters which are directly concerned with the dissemination of odors; engineering problems of odor control by methods of prevention or by air purification; the problem of comparing the cost of such protective measures with the damage inflicted, a matter of economics; and the question of the appropriateness of odors to certain places, a psychological question. These factors are often so mixed and tangled that it is no wonder that the legal and administrative phases of the subject are difficult. Perhaps, the solution of particular problems may be made easier if these different elements of the subject are considered separately under the following heads: (1) Physiology of odors; (2) relation between odors and health; (3) meteorological factors of odor travel; (4) governmental control of odors; and (5) prevention of odors.

The Physiology of Odors.—The speaker has recently had the pleasure of looking over the manuscript of a forthcoming book on "Smell, Taste, and Allied Senses in the Vertebrates", by Professor George H. Parker, of Harvard University, in which a chapter is devoted to the anatomy of the olfactory organs and another on the physiology of olfaction.

There has been some controversy among physiologists as to the mechanism by which the so-called sense of smell is exercised; but it is now recognized that two classes of substances produce nasal stimulation, namely, irritants, which act on the free ends of the trigeminal nerve, and true odors, which affect the terminal cells of the olfactory nerves. This is an important distinction. Some substances, like sulphurous acid, are irritants and have no

* Prof., San. Eng., Harvard Univ., Cambridge, Mass.

true odor; others, like the oil of vanilla, have a true odor, but are not irritating; but some substances, like tobacco smoke, affect both sets of nerves, although this may be due to the mixed character of the smoke.

It appears to be well established that both odors and nasal irritations are caused by actual substances carried by the air into the nasal chamber. The quantity of these substances required to produce sensation is almost infinitely small. The ends of the nerve cells are not uniformly distributed over the nasal passages, and in ordinary breathing the air does not come in contact with them. Sniffing, however, brings the air into those parts where the nerves are located. Diffusion of the air in the nose may carry small amounts of the odoriferous or irritating substances to the nerve cells, and, once stimulated, involuntary sniffing may occur. The air may reach the nerve cells through the nose during inspiration, as in the ordinary process of smelling, or the odors may be carried to the cells from the mouth during respiration, as in tasting food. Many so-called tastes are really odors; holding the nose prevents respiration through it and thus prevents the taste (odor) of castor oil, for instance, from being noticed.

The physical state of the minute particles which produce irritation or odor does not appear to be known. Possibly they are electrically charged. It is certain that they affect the nerves most when accompanied by moisture in the air. "They do not emanate from their source and disperse in all directions as sound and light waves do." They result from evaporation or volatilization and are carried by the air as it moves, being spread through it by processes of mixing.

In the nose the olfactory membrane is covered by mucus into which the olfactory hairs project and beyond which they do not extend. The mucus apparently dissolves the odoriferous particles which thus come into intimate contact with the olfactory hairs.

TABLE 1.—Quantities of Substances Required for Minimum Stimulation.

Substance.	Thousandths of a milligramme per liter of air.
Camphor	6
Ether	1
Sulphureted hydrogen	0.5
Citral	0.5 to 0.1
Heliotropin	0.1 to 0.005
Cumarin	0.05 to 0.01
Vanillin	0.005 to 0.0005
Chlorphenol	0.004
Oil of rose	0.0005
Mercaptan (garlic odor)	0.00004
Artificial musk	0.00004

The quantities of substances required to stimulate the trigeminal and olfactory nerve cells are extraordinarily minute. Many years ago, when studying the odors produced by microscopic organisms in water, the speaker found that oil of peppermint could be recognized when diluted with 50 000 000 times its volume of water, and that the essential oils found in several of the

algæ could be detected in dilutions of from 5 000 000 to 25 000 000. Various devices have been used recently by physiologists in studying olfactory acuity. Some of these olfactometers are most ingenious, especially that of Allison and Katz.*

As a result of various tests, it has been found that certain odors can be recognized in the quantities given in Table 1. Different observers give somewhat different values, as might be expected.

Messrs. Allison and Katz† have given a table, part of which is reproduced herein as Table 2.

TABLE 2.—CONCENTRATIONS OF MILLIGRAMMES OF CHEMICAL PER LITER OF AIR.

Chemical.	Intensity of Odor.				
	Detectable.	Faint.	Noticeable.	Strong.	Very strong.
Ethyl ether	5.833	10.167	14.933	17.667	60.800
Chloroform	3.300	6.800	12.733	28.833	46.600
Ethyl acetate	0.686	1.224	2.219	4.457	6.739
Ethyl mercaptan	0.046	0.088	0.186	0.357	0.501
Pyridine	0.082	0.146	0.301	2.365	5.710
Oil of peppermint	0.024	0.032	0.109	0.332	0.848
Iodoform	0.018	.....	.....	.....	.....
Methyl isothiocyanate	0.015	0.030	0.057	0.108	0.144
Butyric acid	0.009	0.021	0.066	0.329	0.580
Allyl isothiocyanate	0.008	0.012	0.024	0.030	0.201
Propye mercaptan	0 006	0.020	0.028	0.043	0.054
Amyl thioether	0.001	0.007	0.011	0.012	0.015
Artificial musk	0.00004	.....	.....	.....	.....

It would appear from these data that the olfactory nerves are more sensitive than those which give rise to nasal irritation, but it is probably unsafe to state this as a general truth.

In his studies of the odors of organisms in water, the speaker has observed that as odors decreased in intensity they changed in quality. This is probably due to the fact that few odors are pure, that is, due to a particular substance, most odors are mixtures. When these mixtures are diluted, the less sensitive constituents lose their effect first, while the more sensitive ones persist; the result being a change of odor. This is also true in the case of substances which produce both irritation and odor, the odor may persist after the irritation has ceased, or when increasing in intensity the odor is noticed first and this is followed by irritation. Tobacco smoke is an example. There may be mixtures of substances which act chemically on each other, so that the result is actually a different odor, and not merely a mixture of odors. On a more intense scale, it is well known that one odor may mask another and that a strong agreeable smell may be substituted for an unpleasant one. The little known subject of ratios of odors underlies the practice of "deodorization".

Temperature has an important influence on olfactory acuity, an influence partly physical and partly psychological. Heat increases the evaporation and

* "An Investigation of Stenches and Odors for Industrial Purposes", *Journal*, Industrial Eng. Chemists, Vol. XI (1919), p. 336.

† *Journal*, Industrial Eng. Chemists, Vol. XI (1919), p. 338.

volatilization of most odoriferous substances. Cold air drawn into the nose chills the mucous lining and perhaps retards the concentration of the particles in it. Conversely, cold fresh air makes the scent more keen. Cold water drawn into the nose greatly reduces the power of detecting odor.

Another important physiological phenomenon is that of fatigue and exhaustion of the olfactory organs. The continual smelling of an odor exhausts the power to recognize it. This may be a matter of a few minutes, or it may be longer. Every one knows the phenomenon of "getting used to an odor". Every one knows that breathing fresh air removes the last traces of odors and restores the power to recognize those which are very faint. An ocean voyage does this to a marked degree. On approaching the Japanese coast and while still several miles from it, the speaker will never forget how, after ten days on the Pacific, he enjoyed the "land smell", the smell of the "good brown earth".

The quality of an odor is usually designated by reference to the substance with which it is associated. It is different from taste, of which there are four clearly marked qualities: sweet, sour, salt, and bitter. Odor designations are numberless and constantly changing, but attempts have been made to classify them. Haller's classification has nine groups, as follows:

1.—Etherial odors: odors of fruits, beeswax, ethers; three subdivisions.
2.—Aromatic odors: odors of camphor, cloves, lavender, lemon, bitter almond; five subdivisions.
3.—Balsamic odors: odors of flowers, violet, vanilla, cumarin; three subdivisions.
4.—Ambrosial odors: odors of amber, musk; two subdivisions.
5.—Alliaceous odors: odors of hydrogen sulphide, hydrogen arsenide, chlorine; three subdivisions.
6.—Empyreumatic odors: odors of roast coffee, benzole; two subdivisions.
7.—Caprylic odors: odors of cheese, rancid fat; two subdivisions.
8.—Repulsive odors: odors of deadly nightshade, bedbug; two subdivisions.
9.—Nauseating odors: odors of carrion, feces; two subdivisions.

Another classification (Henning's) has six groups, as follows:

1.—Spicy odors, such as those of fennel, sassafras oil, anise, and cloves.
2.—Flowery odors, such as those of heliotrope, cumarin, and geranium oil.
3.—Fruity odors, such as those of oil of orange, citronella, oil of bergamot, and acetic ether.
4.—Resinous or balsamic odors, such as those of turpentine, Canada balsam, and eucalyptus oil.
5.—Burnt odors, such as those of tar and pyridin.
6.—Foul odors, such as those of carbon bisulphide and hydrogen sulphide.

All these groups are artificial and unsatisfactory. They have a psychological rather than a physiological basis.

Relation Between Odors and Health.—Do odors affect health? This question cannot be properly discussed without drawing a distinction between true odors and irritants and without a clear understanding of what is meant by "health".

In a physiological sense, meaning a condition of the body in which it operates normally, the effect of odors on health is ordinarily slight; often there is no effect. Yet intense odors may cause reflex actions of the digestive, muscular, and secretory systems. A vile odor may make one sick to his

stomach or cause him to close his nostrils with his fingers, or run away. Even bad odors, however, do not cause disease, as the term is ordinarily understood; they do not shorten life. The irritants may cause smarting sensations and respiratory discomfort and probably are more closely related to health than true odors. Offensive odors may cause people to refrain from breathing deeply, may cause loss of sleep, restlessness, loss of appetite, and general malaise. These are certainly matters which appertain to health, and to some people they are of serious import.

If, however, the word, health, is extended to include the psychological as well as the physiological, if it includes human comfort as well as bodily functions, then odors do have an important influence on health. In addition to what has been mentioned, odors have strong powers of suggestion and give pleasure, discomfort, or disgust, as the case may be. They may interfere with one's quiet and repose.

Psychologically, people recognize the appropriateness of certain odors to times and places. The smell of fried onions in the kitchen may cause no complaint, but the same smell in the living room or sleeping room is objectionable, at least until nasal fatigue makes one used to it. The combination of nasal fatigue and a sense of the appropriateness of odors makes working under various conditions bearable, in a sewer, a slaughter-house, a garbage plant, a snuff factory, a candy store. Furthermore, such odors do not appear to affect permanently the health of the workers. The odors of a tannery in a residential district, of an oil refinery near a beach resort, of a garbage plant, sewage works, or rendering establishment in or around human habitations, and of a house drain in a living room, are regarded as inappropriate and are quite certain to cause complaint. Psychologically, also, it makes a difference whether the odors are local. In a village where all the people get their living from a pulp mill, no one seriously objects to the pulp-mill odors, but let a pulp mill move into an established community, and the residents not connected with the establishment will regard the odors as a nuisance. Some odors also are regarded as a necessary evil, such as the smell of manure around the farm, and the smell of fertilizer on the garden; while the same odor suddenly appearing from an unknown source causes complaint. People have become accustomed to the smell of coal-burning furnaces; they have not yet become accustomed to the smell of oil-burners.

People object to certain odors because of their suggestiveness, and this raises the question as to whether bad odors may be taken as an index of unhealthful conditions. There seems to be only one answer to this, namely, that an odor is a useful, but not always a safe, guide. The sense of smell in animals is utilized largely in their search for food. In human beings, it is used in the selection of food. Human beings rebel at the odors associated with putrefaction, a matter of instinct which warns against eating unsafe food. Odors of decomposition in drinking water are also warnings which should be heeded. The odors of the algæ, however, are objected to not because they suggest that the water is unsafe, but because they are out of place. Where food and water are concerned, the warnings of bad odors should be heeded, but the absence of bad odors is not a proof of safety. Odors as guides

to unhealthful atmospheric conditions are much less trustworthy. The extremely minute particles of odor-producing substances will travel through the air to far greater distances than bacteria, which, although tiny in themselves, are vastly heavier than the odor particles. It has been proved that the odor of a sewer or house-drain in the air of a room is practically no indication of the presence of bacteria from the sewer or the drain. It has been stated that such odors may be accompanied by minute quantities of chemical substances, which in larger doses are dangerous to the human system, but it has not been proved that these minute quantities are dangerous to health, although on this point Science has not yet spoken the final word.

The odor of coal-gas in a room has come to be regarded as an index of danger, the real danger being the odorless carbon monoxide; but water-gas, which contains much more carbon monoxide than coal-gas, has much less odor, and, for this reason, gas poisonings are more frequent now than before water-gas was largely substituted for coal-gas.

In spite of its shortcomings as an index of danger, in spite of its limited physiological bearings and its erratic psychological relations, the sense of smell is one which cannot be ignored, and human beings continue to insist that health and comfort be kept together and not separated artificially, as for the purpose of scientific discussion. The "health and comfort of the people" is an expression which not only has a great human urge back of it, but which has been found to stand the test of the Courts. In the speaker's opinion, the word, "health", used as a basis of the exercise of police power, should be given its broader and not its narrower meaning. In this connection, it is well to remember the following words taken from the first public utterance of the first State board of health in the United States, that of Massachusetts, in 1869:

"We believe that all citizens have an inherent right to the enjoyment of pure and uncontaminated air and water and soil; that this right should be regarded as belonging to the whole community; and that no one should be allowed to trespass upon it by his carelessness or his avarice or even by his ignorance."

Meteorological Factors.—Inasmuch as odors and nasal irritations are caused by actual particles (it matters little whether they are regarded as gaseous, liquid, colloidal, or solid), transported by the air from their source to persons affected, a study of odor travel is very largely a study of meteorology, especially air movement.

First, moisture in the air intensifies odors. It provides a solvent for certain substances which otherwise might not be given off at the source, and it more readily conveys the odoriferous substances to the nasal mucus. A dry air tends to harden the surface of the mucous lining and protect the olfactory hairs. A warm air also intensifies odor, as a higher temperature hastens evaporation and volatilization as well as the sensitiveness of the nerve endings. A low barometer also hastens evaporation. Rain and snow act as natural air washers and purify the air. Ozone is said to have an oxidizing effect, but little is known of this. It may be that there are also electrical conditions which have an influence on the almost molecular particles which produce odor. The greatest factor, however, is air movement, a factor which in itself is

dependent on temperature, barometric pressure, humidity, and other physical conditions.

Of the air movements, first consider those gentle movements, unmeasurable by the most delicate meter, due largely to temperature difference. They can be observed by movements of smoke and dust particles and by cooling effects on the skin. It is these almost insensible convection currents which spread the odor particles from their source for short distances in all directions. Very few odors are strong enough to be carried far from their source in this manner. Next, in order, are the gentle variable breezes which waft the odors to distances of a few hundred yards. They are usually intermittent, and not always constant as to direction, but they cover a wide angle. At a distance one gets the odor now and then. Finally, there are the winds, stronger and more constant, which carry the odors in a definite direction for long distances. The angle in this case is narrow. This pollution of the air by odors is not unlike the pollution of the water of a lake by sewage. The pollution may spread out slowly like a fan or, more accurately, perhaps, like a cone, or it may be carried by a strong current in a long narrow streak.

The speaker is not sure but what the author is right when he says that odors cannot be subjected to mathematical analysis. May it not be possible to divide odors into groups of different magnitude, define them in terms involving the velocity of the wind, the angle of the sector, or cone of pollution, and the distance from the source? The angle of the sector is a function of the veering of the wind, that is, the deflections of the wind from parallel lines, due to all kinds of minor local causes, which have a greater influence when the wind velocity is low than when it is high, as the higher winds are controlled by larger and more general causes. No classification should be attempted, however, until many careful observations have been made.

Topography, of course, is an important element in odor travel. Air travels through valleys, "draws" through breaks in hills, and is obstructed in its flow by forests and buildings. In any mathematical formula, these factors would enter as a coefficient which would vary with local conditions.

The elevation of the odor source has an important influence on the travel of the odor. Odors escaping from tall chimneys may be unnoticed on the ground near the base of the chimney, but may be very noticeable a mile away. On certain days, when the sun is shining on the ground, the air in the lower strata becomes heated and tends to rise; consequently, the odors become lost in the upper air. At night, the conditions may be reversed; the odors lie lower. The water surface of a lake or harbor influences the vertical movements of air in ways that are well known. The importance of vertical currents is more appreciated since the aeroplane has come into use. The humidity conditions at night are also more favorable for odor travel. The effect of damp, muggy days on the intensity of the odor nuisance is too well known to need further mention. Muggy conditions not infrequently accompany a lower barometer, a factor which also tends to facilitate odor production.

Governmental Control of Noisome Odors.—According to Judge Jeremiah Smith, late of the Harvard Law School, a nuisance is whatever the Court decides is a nuisance. Attempts have been made to define a public nuisance,

but in the last analysis the decision goes back to the opinion of "twelve good men and true" in a particular case. As far as the law is concerned, an odor nuisance, if action is taken by the Government under police power, must be proved to affect the "public health, safety, morals, or the like". The modern tendency is to extend the police power to cover public welfare and to let the phrase "and the like", cover public comfort, quiet, and repose. Certainly, it will be admitted that bad odors and irritating fumes are a public discomfort. In such matters as these, the opinion of the layman is often sounder than that of the expert.

American cities are growing, and as they become larger it is right that the police power should be extended and applied more severely. A slight odor affecting a large population may be as much of a nuisance as a very bad odor affecting a small population; for in the large population there is a greater chance that more persons susceptible to the slight odor may be present.

Bad odors which are spread over large residential areas, may depreciate property values, but the speaker fails to understand how this can be properly regarded as coming within the scope of the police power. In board of health hearings, however, this argument is commonly introduced. Claims for damages to property are for the Civil Courts to adjust. Lawyers know, however, that police power action by a health board is a help in a suit for damages, and not infrequently this is the motive back of nuisance complaints. One of the greatest difficulties in the governmental control of nuisances is to know whether the complaints are really sound.

Another serious difficulty in such control of objectionable odors from industrial works is that the nature and extent of the odor and the certainty of its being a nuisance cannot legally be determined in advance. In the Staten Island garbage case, referred to by Mr. Tribus, the Governor of the State of New York decided that the State's power of abatement could not be exercised until the works had been completed and had been found actually to be a nuisance, in spite of the fact that an investigation by the State Health Commissioner had shown that a nuisance would probably occur. This brings up the necessity of the exercise of greater care by local authorities in granting building permits for industrial plants. Local governments are usually glad to have a new industry established and readily grant a permit for building, often without bringing the matter to the attention of either the local or the State board of health. In the case of chemical manufacturing, the permitted establishment may create an odor which causes widespread and justified complaint. Then comes the difficult decision. Shall an established industry be closed? Shall the economic advantage to the community be tacitly considered in the exercise of police power? Shall economic advantage be considered as offsetting public discomfort? Or, if the case is one in which the odors can be prevented, how far shall the manufacturer be made to correct them? And if the industry is a new one, how long shall suffering citizens be made to wait while new devices for odor reductions are being tried? The lesson taught by many unpleasant experiences of this kind appears to be that it is wise to exercise greater caution in the location of industrial works which involve chemical processes, and to limit them to certain districts or zones.

The speaker was a member of the New York Commission on Building Districts and Restrictions, and his studies at that time led him to believe very strongly in the zoning idea. Zoning alone, however, is not enough. The Staten Island garbage plant was located in an established industrial district, but the trouble was that the odors "would not stay zoned". One way of avoiding the difficulty would be to require local authorities, before granting a building permit to a chemical industry, or any industry likely to cause public offense, to receive a letter of advice from the State department of health or other competent authority, such letter to be published and thus brought to the attention of the people before action is taken. Although the layman is as good a judge of what offends his nose as a sanitary expert, the expert is better able to judge in advance of the probability of a public nuisance being created. No such advisory action is needed in regard to the location of certain nuisances which have been adjudged by the legislature or the Courts to be nuisances *in esse*. Certain industries have well earned the title of "offensive trades", abattoirs, soap factories, rendering works, tanneries, and the like, as well as sewage works and garbage works. Already, the laws in some States require the location of such works to be approved by a sanitary authority. Just as health departments establish lists of diseases dangerous to the public health, so should they establish lists of industries which threaten the public health and comfort.

When a manufacturing plant, by disseminating irritating fumes or odors, becomes a public nuisance, the demand is usually made that it be shut down, heavy fines levied, or some other penalty inflicted. There are cases where such punishment is just and where the nuisance cannot be abated in any other way. In many instances, however, the elimination of odors is a difficult matter, and those who operate the plant do not know what to do; they do not feel sure that the expenditure of money for certain devices will accomplish the result. In other words, what they need is sound advice, not punishment. Unfortunately, the Engineering Profession has never developed specialists in odor prevention. This appears to be a field worthy of serious consideration. Combined with smoke and dust prevention and ventilation, it should furnish ample scope for a career for a young man who has a knowledge of chemical engineering, physics, meteorology, and sanitation. For many years State departments of health have been in a position to give advice in regard to the purification of water and the disposal of sewage and, in the speaker's judgment, the use of this advisory power has accomplished more than the sterner measures of the police power. The disposal of sewage, however, is practically a single problem, although, of course, it has its complications, and it is also a public problem. In the case of chemical manufacturing, the situation is different. The problems are very complex, the works are privately owned, and the processes are often secret. Hence, the consulting specialist is in a better position to handle the problem than the sanitary department of a State board of health.

Not infrequently, odors from industrial plants are due merely to bad management, carelessness, or sloppiness, and the correction of these faults

often leads to greater profits to the concern. The escaping fumes may be waste products, but they are sometimes valuable and worth saving.

New lines of manufacturing are constantly being taken up and new problems are continually arising. Thus, in Massachusetts, several oil-refining plants which represent investments running into several million dollars, have recently been built. Some of these plants are handling Mexican oil which contains much more sulphur than the common American products. The refining processes have given rise to odors and irritating fumes of an offensive character, which, in one notable instance, spread over a wide area and caused a serious public nuisance. Recognizing the novelty of the problems to be solved and the importance of the industry to the community, an order requiring the works to close was stayed from time to time, in order that the effect of new devices might be ascertained. Finally, however, there appeared to be no other course, just to the people, than that of closing the works until certain advised alterations could be made.

Odor Prevention.—This leads naturally to the subjects of odor prevention, air purification, and air analysis, which are too detailed for the speaker to discuss. Various methods are now available. The sedimentation of dust, the electrical precipitation of dust, acid, fumes, etc., by the Cottrell system, the washing of air by drops and sprays of water, the burning of organic dust at high temperatures, the filtration of air through cloth, the ventilation of buildings, the removal of odors absorbed by floors, walls, and fabrics, by washing and by the use of a compressed air blast, the use of disinfectants to prevent or arrest decomposition of organic matter, the application of sunlight, the use of chemicals to alter the character of the odor-producing substances—these and other methods, used singly or in combination, as the situation may demand, furnish means by which almost any industry may be made amenable to reasonable standards of health and decency.

Stephen DeM. Gage,* Esq.—Both the author and Professor Whipple have pointed out that much trouble might be avoided if some method was devised for locating odor-producing industries where they would be least offensive. The situation which exists to-day in certain parts of Providence, R. I., and the adjoining communities, is the direct result of such lack of foresight.

About ten years ago, the Chamber of Commerce and other public bodies endeavored to increase the importance of the Port of Providence, and a number of the large oil companies were induced to establish extensive receiving and distributing stations at the head of Narragansett Bay. To-day, Providence is one of the largest oil ports in New England. In connection with the operation of these oil stations, two companies established plants for the separation of crude oil into its component parts by distillation, and at one of them practically all the processes used in the refining of oil products are carried out. These two plants are about 3 miles apart, on opposite sides of the Providence River, and within about 4.5 miles from the center of the city.

* Chemist and San. Engr., State Board of Health, Providence, R. I.

Unless plants of this kind are completely equipped with special devices to control odors and are carefully operated, offensive nuisances are likely to arise from odors which at times may travel considerable distances. Shortly after these plants began operation, complaints of offensive odors in adjacent residential districts were received, which increased both in number and in vehemence, until the Legislature directed the State Board of Health to investigate and report on the subject. During the progress of this investigation much was learned about odors of this kind and about their travel habits.

The odors from oil-distilling and refining plants are probably of a mixed character, partly gaseous and partly colloidal. They are variously described as "burnt oil", "burnt rubber", or "sweetish burnt rubber." Observers who have had laboratory experience and chemists generally use the latter term as most definitely expressing their impressions. The character of these odors varies considerably with the dilution. Near the source when they are intense, they have the characteristic odor of rotten eggs, or sulphide odors. As the distance from the origin increases, and they become more dilute, they take on the odor of burning rubber, with a sweetish or slightly burnt sugar flavor. With more dilution the rubber constituent disappears, and the odor may best be described as that noted when a baker's oven full of well browned bread is opened. When still more dilute, these odors are like that of slightly scorching paper. At first, these changes in the character of odors from the same source led to considerable confusion. In one instance, the speaker located a not unpleasant odor on the leeside of a large bakery, which was attributed to that source, and was surprised to find that this odor was much stronger on the windward side of the supposed source; and it became decidedly offensive as it was traced to its origin.

The reason for this change of character in odors is undetermined. It may be that odors are a blend and that one component is diluted out sooner than others. It is well known, however, that some apparently simple odors change in character with dilution. The characteristic odor of kerosene is recognized easily by almost every one, but when greatly diluted it is more likely to be described as some kind of perfume.

It may be of interest to mention that during the investigation mentioned considerable care was taken to obtain comparable observations from different observers. The acuteness of the olfactory sense varies widely in different people and in selecting observers for this work, men were chosen whose sense of smell was reasonably alike. These men were then taught to record odors of similar intensity in a similar manner. The scale was the same as for recording odors in water analysis, "very faint", "faint", "distinct", "strong", and "very strong", the distinct odor being one which would be readily detected by almost every one and which would be disagreeable to most people.

From observations, the speaker believes that the travel distance of odors of this character is mainly a function of two factors: the amount of odor produced at the source, and the velocity of the wind. There are other factors, however, which apparently enter into the problem. Weather conditions affect the travel habits of odors to a certain extent. The theory that sunlight may have a deodorizing effect may account for the fact that odors of this kind

are more troublesome at night or on days when there is a fog or heavy mist, than on clear bright days. As instances of odor travel, the following observations might be recorded:

1.—Night, weather clear, wind from 3 to 4 miles per hour, travel distance about 1.5 miles, area affected about 3 sq. miles.

2.—Day, rain, wind about 4 miles per hour, travel distance about 4 miles. In this instance, the odor was carried across the water about 2 miles before affecting a residential area of about 2 sq. miles.

3.—Night, cloudy with light showers, wind from 4 to 5 miles per hour, travel distance about 2.25 miles, area affected about 5.25 sq. miles.

4.—Night, cloudy, wind about 5 miles per hour, travel distance about 4.5 miles, area affected nearly 10 sq. miles.

5.—Night, weather clear, wind about 9 miles per hour, travel distance about 1.5 miles, area affected approximately 3 sq. miles.

6.—Night, weather clear, wind about 9 miles per hour, travel distance about 2.25 miles, area affected about 5 sq. miles.

One other interesting observation may be mentioned in which the direction of the wind was such that strong odors from two sources mingled and fortified each other. The characteristic odor was noted at a travel distance of 2.5 miles from the nearest source and about 6 miles from the more distant source. At this time a residential area of about 11 sq. miles was affected, in addition to an undetermined area over the water. This odor occurred at night, in clear weather, and with a wind velocity of about 5 miles per hour.

It should be noted that the wind velocity is that recorded at the Government Meteorological Station, 2 to 6 miles from the areas in which the observations were made. These figures are the only ones available, but the possibility that the wind velocity might be different in the two localities must be taken into consideration in any interpretation of the observations noted.

The author has pointed out that there are many apparent peculiarities about the travel of odors. With little or no wind, they do not appear to travel far from their source, and if the wind is strong, they are apparently dissipated and not troublesome at a great distance. In some instances, they may travel high, although at other times, with apparently similar conditions, they will travel low. There are a number of observations where these odors, quite offensive a mile or more away, could not be noted near the point where they originated. In one instance, an odor was traced from hilltop to hilltop for a considerable distance, but could not be detected in the valleys. Other cases have been observed of an odor settling in air pockets and remaining an offense long after it was discharged from its source. This is most likely to occur on damp, foggy nights with little wind. It has been also frequently observed that these odors will be strong on certain streets and perhaps cannot be detected in parallel streets on either side. Variations in odor intensity in near-by localities can be attributed only to differences in air currents. Such variation may be responsible for a wide difference of opinion among the residents of certain sections as to whether a certain industry is offensive or non-offensive, and such differences must

often be proved and reconciled before relief from offensive conditions can be obtained.

Another phase of the oil problem becoming prominent, which may become of greater and more far-reaching importance than odors from oil-distilling and refining plants, is the probable effect of the substitution of oil for coal in power and heating plants. There is no question that oil fuel is easier to handle, easier to store, and more economical than coal. The bulk of fuel oil used in New England cities is from Mexican crudes which carry about 4% of sulphur. The fuel oil contains more than 4% of sulphur, as much is left behind when the naphtha and gasoline are removed. If the combustion of this fuel is complete, the sulphur is converted into sulphur dioxide, an irritating gas which is discharged into the air. If the combustion is not complete, which is frequently the case, a part of the sulphur passes off as hydrogen sulphide or other sulphide gases, together with some partly burned oil, all of which are extremely offensive. Many oil-burners have been constructed in fire-boxes designed for soft coal and it is practically impossible to obtain complete combustion. Furthermore, some of the oil-burners now on the market are defective and cannot be operated to the best advantage.

For purposes of illustration, assume a community using 1 000 000 bbl. of oil fuel per year. This is not unreasonable, and the speaker knows of a single power plant now using this quantity. Only 4% of sulphur would amount to about 30 000 lb. of sulphur burned per day. With complete combustion, this would be equivalent to 60 000 lb. of sulphur dioxide gas discharged from the stacks every day. The speaker does not know that this sulphur dioxide when diluted with the air would directly affect the health of the people; he does believe, however, that if the oil-burning plants were concentrated and near enough to the residential section, it would cause more or less serious irritation to the nose, throat, and lungs of a certain portion of the population, and perhaps render these people more susceptible to other diseases. The speaker also believes that under prevailing conditions at many oil-burning plants to-day, the odors of incompletely burned oil and sulphides would be so frequent that this community would not be counted a desirable place in which to live. This is the problem to be solved in the near future. This problem and all odor problems can be solved, but the engineer and the chemist must first build a solid foundation of scientific facts before anything definite can be accomplished.

I. S. Osborn,* M. Am. Soc. C. E.—The subject presented by the author is a timely one, to which practically no attention, study, or research has been given. Had a small part of the cost of litigation in connection with suits brought to eliminate nuisance from odors been expended in study and research, there would have been accomplished far more toward the elimination of odors than has been achieved by Court decisions.

Since the speaker has had more or less intimate contact with all the plants mentioned by the author, the points raised in his paper relative to garbage disposal works and the odors produced are of especial interest.

* Cons. Engr., Cleveland, Ohio.

In dealing with the problem of garbage reduction, one must necessarily consider somewhat the size to which this industry has grown in the United States. In an investigation for the United States Food Administration in 1918, the speaker found that 29 of the larger cities disposed of their garbage by the reduction method, and produced annually 72 000 000 lb. of grease and 150 000 tons of fertilizer tankage, valued at $11 000 000. These figures demonstrate that the industry deserves considerable attention. The nature of the business, as well as the attitude of the men or the companies engaged in the operation of disposal plants, has not given much incentive to develop the industry along scientific lines, with the result that it has grown to this size without much assistance from the Engineering or Chemical Professions.

The plants have not been perfect either for the making of all possible recoveries or the elimination of nuisance from odors. However, the industry should not be condemned, but should have the efforts of engineers and chemists toward development whereby it can be operated without nuisance and without the objections due to past performance.

In this discussion of garbage reduction plants the odors considered are those which will travel or give rise to complaint in surrounding communities.

The reduction methods for garbage disposal vary in detail, but the majority of plants use the digester and dryer systems, in which the garbage is cooked in digesters, with live steam, after which it is pressed and dried.

In plants of this type the sources of odors are from the raw garbage, exposure of material during process, finished products, leaks in apparatus, vents from digesters, and gases from direct heat dryers. The greatest source of objectionable odors are the gases vented from digesters, or the gases from the dryers. The vent gases are the most penetrating and objectionable, but are more easily controlled and treated than the much larger volume of sweetish or caramel odors from the dryers. The odors from the raw garbage, the plant, and the finished products can be controlled and, with proper design and operation, should not give cause for nuisance.

In 1915, the speaker made an investigation and report to the Committee on Street Cleaning, Board of Estimate and Apportionment, New York City, on the elimination of odors from the Barren Island Disposal Plants. At the time of this investigation practically no data on this particular subject were available. This investigation covered the three plants operating at that time on Barren Island, namely, the plants of The Sanitary Utilization Company, which were then used for the disposal of garbage under contract with New York City; the plant of the Thomas F. White Company, which was operated for the production of tankage by drying the digested garbage; and the plant of The Products Manufacturing Company, which, under contract with the City of New York, disposed of dead animals and meat offal, and also rendered garbage collected from hotels and restaurants.

The assistance of The Central Testing Laboratory, maintained by the city, was obtained for analytical work in making these studies. The investigation which covered a period of about four months was for determining the necessary steps to remedy and eliminate the objectionable odors from these plants. Tests were made to determine the source of the odors, and the volume of the

gases carrying the odors, as well as the methods that might be adopted to deodorize the gases. The tests were made both in the field and in the laboratory, and, except the chemical analysis of gases which was made in the laboratory, the larger part of the work was done at the plants while they were in operation.

These tests involved the development of methods in regard to which no precedents and data were available. It was found that the apparatus secured for this work was not adaptable and it necessarily had to be remodeled, calibrated, and tested. Search was made for information on this subject as well as on kindred subjects. Although the work was not carried to the extent desired, the results of this investigation were, in many ways, satisfactory, many facts were established, and information of great value was gained regarding the design and operation of such plants.

Analyses of the gases given off from the vents of digesters before and after passing a barometric condenser showed that the carbon dioxide, which amounted to 45.2% before passing the condenser, was reduced to 6.2% after passing it, which indicates the efficiency of the condenser in absorbing condensible gases. The odors from digesters were found to be due primarily to the sulphur compounds and to a less extent to essential oils.

Tests to deodorize the vent gases entirely eliminated the odors by washing the gases in a solution containing small quantities of sodium and calcium hypochlorite (chloride of lime). It was found that 10 cu. ft. of gas could be deodorized in 150 cu. cm. of calcium hypochlorite solution containing 4 parts of available chlorine in 1 000. Gases treated by heating alone were not deodorized, but when heated to 1 100° Fahr., the sulphur compounds changed to sulphur dioxide which was soluble in water; so that by washing after heating, complete deodorization was obtained. The commercial application of the calcium hypochlorite solution in washing gases was difficult in practical operation, and the method of heating and then washing showed the greatest possibility of application.

Since this investigation, developments have been undertaken whereby gases carrying odors are treated with chlorine gas. The results have not yet been determined by analysis, although where the chlorine gas has been applied to digester vent gases, the characteristic odor is not noticeable at the point of discharge. It has not been determined whether the odor is disguised or masked by the chlorine gas or whether chemical action deodorizes the gases.

Where the direct heat dryers were used, the volume of gas given off was excessive. From 175 000 to 200 000 cu. ft. of gas per min. escaped from the dryers in the plant of the Sanitary Utilization Company. The cause of odors in dryer gases is due largely to the scorching or burning of the material and a sweetish and caramel odor is produced, due to the scorching of sugars. In making tests, dryer gases were completely deodorized by washing, the elimination of odors by scrubbing being in proportion to the degree they were washed. It is difficult in washing gases to eliminate the odor entirely, although it is possible. Heating the dryer gases to a temperature of 1 800° Fahr. eliminated the odor; they were also completely deodorized in calcium hypochlorite solution.

Experiments to ascertain whether the odor could be eliminated by the dilution of gases with air, showed that the odor was still distinct in 1 part of dryer gas with 400 parts of air; that it is characteristic of this gas to travel more or less in pockets and not diffuse readily with the air; and that it is not feasible to depend on the dilution of dryer gases to eliminate odors.

The elimination of odors from handling materials, as well as plant and room odors, is a problem to be considered in the design of plants. With suitable methods adopted for their control, and attention in operation, they should not give rise to objection. It is fundamental, however, in the operation of disposal plants, that the first object should be the elimination of the production of odor, thereby making it unnecessary to provide means for deodorizing.

The statement made by Mr. Tribus that, although it was possible to operate the Staten Island plant without offense, it was not practical, is not borne out by fact. The financial results obtained by the company would have been greater if the plant had been operated without offense.

The Staten Island plant uses the Cobwell process, which differs from the digester system. In the digester system, the garbage is sealed in tanks or digesters and live steam is admitted for cooking. The digesters must necessarily be vented to insure a supply of steam for raising the temperature of the material. After digestion, the material is pressed, and the solids are dried. In the Cobwell process, a reducer with a steam jacket is used, and the garbage in this reducer is submerged in a solvent for the grease, which acts also as a dehydrating agent. Water or steam vapors combined with solvent vapors leaving the sealed reducer pass through a vent pipe to the condenser, where they are practically all condensed. Tests showed that the vapors given off from the reducers, after passing the condenser, were odorless.

There is no question regarding the odors referred to by Mr. Tribus from the Staten Island plant. From the speaker's observation they were detected at a distance of from 3 to 4 miles. The odor was not the same as that from the plants on Barren Island, where the digester and dryer systems were used. In all probability, most of the odor given off was the result of the operation of the plant without proper sealing, which allowed the gases to escape directly to the atmosphere without passing through the vent line to the condenser. This is borne out by the results of investigation as well as from operation, and is the cause of the great loss in solvent which resulted from this practice.

The speaker was in charge of this plant during the first two months of operation, during which time it was found, not only possible, but practical, to operate without producing gases having odors. During this time, from daily inspection and study, the odors emanating from this plant were never noticed off the property on which it was located. The experience of the company in regard to loss of solvent demonstrated that it did not pay to permit odors to escape, for with the escape of any gas from the reducer, there was a corresponding loss of solvent.

The statement made by Mr. Tribus that slaughter-houses have gradually and almost ceased to be offensive is not fully borne out by investigations of this industry. In many cities, as in former years, they are either tolerated

as a necessary evil, or there is continual agitation and occasional litigation in regard to them.

Mr. Tribus states that "the real point of importance, however, is the distance that smells travel and their actual effect on human beings". Is it not of greater importance to determine the source and the necessity of the odor. In most cases, the source can be determined and the emission is unnecessary.

A survey of the past efforts and policies of municipalities with reference to this subject, reveals a lack of attention given to the problem. As long as municipalities expend no greater effort toward an engineering solution of the garbage disposal problem in the design of municipal plants, and continue the practice of awarding short-term contracts for the disposal of garbage, whereby the contractor must charge off his investment during this short term, attempt to pay dividends from the earnings under the contract, and, at the same time, meet competition as to price, just so long will the same results be obtained as at present, from a large number of plants.

This statement should not be taken to mean that all disposal works should be municipally operated, but each municipality should control not only the operation but the initial outlay in order not only to safeguard the city against objectionable methods, but from an economic standpoint as well. The continued unsanitary results, agitation, and litigation that have accrued are only natural, and so long as present practice is continued, so long will objections and litigations continue.

The statement by Mr. Tribus that the garbage reduction plant on Barren Island was "for years synonymous with stench", is true, but he is mistaken in that the plant was closed due to legal action. It was closed because the owners did not secure a renewal of their contract with the city. An injunction, however, was granted forbidding the operation of The Products Manufacturing Company's plant on Barren Island, where, under contract with the City of New York, dead animals were rendered. The injunction prevents only operation whereby a nuisance is created, and the plant is still operated, and from all intents will continue to be operated until it is proven a nuisance. Since this injunction was granted, the City of New York has awarded a new contract to the same company for the disposal of animals.

It would seem that greater results could be obtained if the public would look to the city for improvements and relief rather than to the Courts. "Control by anticipation" raises a difficult question and it is doubtful whether little would be gained, as compared to the results that could be obtained if the responsibility for securing the best method were placed on the municipality.

The developments to date in the elimination or non-production of odors have not resulted from any powers that could be granted pertaining to control by anticipation, but from adverse rulings and Court decisions, making it necessary to improve conditions in order to safeguard investments. There is a possibility that control by anticipation would have a tendency to retard development.

Little was known about conducting garbage reduction plants until the municipalities entered the field. Some advance has been made, from necessity

more than from actual study and attention to the development of the systems. When the same attention is given to this problem, as is given to many other municipal problems, and plants are constructed as permanent investments, advancement may be expected.

RUDOLPH HERING,* M. AM. SOC. C. E. (by letter).—The writer is pleased that the author has presented the results of his experience in regard to a subject which has been surrounded by much indefiniteness, ignorance, and prejudice. More facts based on reliable data were needed to form a fixed foundation for judgment, some of which the author has supplied.

Sentimental and personal perception play a large rôle in this subject; but thorough analyses and more impersonal data will help to reach useful conclusions.

Seven years ago, the writer presented a paper before the American Public Health Association on "The Prevention of Odors at City Refuse Disposal Works". As some of the data contained therein may contribute toward an explanation of this subject, a few of them will be repeated.

An odor is perceived by the stimulation of a small area, less than that of a one cent piece, near the upper end of the nasal duct. The normal excitation is caused by the impingement thereon of molecules of matter, either in a solid, colloidal, liquid, or gaseous form. That odorous air absorbs more heat by the addition of these molecules than pure air, was proved by Tyndall. That its specific gravity was increased sufficiently to retard the diffusion was proved by Tigerstedt, who likewise proved that odorous vapors are condensed by absorption at the surface of glass, paper, water, skin, and clothing. Odor molecules detach themselves from the surfaces by evaporation, oxidation, or by hydrolytic decomposition, and may be carried some distance in currents of air.

Some scientists have believed that only gases stimulate the olfactories. Others have demonstrated that liquids, such as sulphate of magnesium, also convey odors. Sharks have a well developed sense of smell.

Odors can be perceived more readily when the air is moist than when it is dry. A dry membrane in the nostrils cannot detect odors, nor does it always respond when the nostrils are completely filled with a liquid, even with eau de cologne. Some persons are incapable of detecting certain odors, such as vanilla, violets, and some faintly burning vegetable matters. The olfactories can tire of some odors and fail to respond; and yet at the same time they can perceive a sudden appearance of other odors. Nagel found that two or more entirely different odors may cause a composite odor, entirely different from either of the originals. Four grammes of iodoform can be made almost inodorous by 200 mg. of Peru balsam, as proved by introducing the two substances separately into the two nostrils. It was also found that the odors of paraffin introduced into one nostril will completely neutralize the odor of rubber, when a certain portion is introduced into the other nostril.

Prejudice has terminated in lawsuits, at times, as evidenced by complaints made of odors of burning garbage, when the actual cause was neighboring

* Cons. Engr., Montclair, N. J.

plants producing other offensive odors and when, in a new plant, smoke was seen to rise from the incinerator chimney and the plant was only being tested with preliminary coal fires.

Further, it must be realized that the odor particles are of different sizes. They are largest when in solid and smallest when in gaseous form. The odors escaping from incinerators are due usually to unburnt solid particles. As long as they drift in the air current from the chimney they will be noticeable, even for miles, in the form of, as it were, invisible clouds. The writer remembers such a case in Staten Island when suddenly in a clear sky and on an elevated bluff a strong burnt-garbage odor was apparent, brought by a gentle wind current straight from a refuse incinerator about two miles distant. It is evident that in discussing the question of odors many fundamental facts must be considered.

The intensity of odors is affected by temperature. If organic matter is burned at about 1 800° Fahr., no odor will result, nor is such matter offensive when it freezes. The most intense odor generally results between temperatures of 90 to 150° Fahr. Dryness likewise controls odor intensity, as has already been stated. In a dry climate, odors disappear rapidly.

Odors arising from gas particles which can easily decompose in the air, such as sulphureted hydrogen, disappear more quickly than when they arise from solid or colloidal particles.

From splashes or sprays the odors from sewage are increased when not only gaseous, but also colloidal, particles are thrown in the air, and drift quite a distance. Air from filters, sprinkled with putrefying sewage is often foul-smelling and is noticeable much farther than the air drifting over a quiescent sewage bed. Dilution of the foul air from the dryers at garbage reduction works, in the proportion of 1 to 500, has destroyed its odor.

When sewage containing odorous gases in solution or suspension, is discharged in streams, an odor has been perceptible near the water surface, even several miles below the plant. The odors after their escape, however, disappear very quickly, as they consist chiefly of gases, and not of colloids or solids.

As already stated, odorous particles suspended in the air, when adhering by absorption to surfaces of walls, clothing, etc., may persist for a long time. They can be removed by brushing and by washing down with blasts of compressed air directed against the surfaces. They can also be removed from clothing by exposure to sunlight.

From the facts known at present it is possible to reduce materially, and even prevent entirely, the odors arising from refuse disposal and sewage works, by a careful study of the specific conditions.

OLIN H. LANDRETH,* M. AM. SOC. C. E.—A consideration of the travel habits of odors will readily indicate that they are lawless creatures, going with the wind which "bloweth where it listeth"; still, in their travels, they must be placed in the class of "short haul" rather than "long haul" traffic.

* New York City.

However, in this "short haul" travel, odors are no respecters of persons, nor of boundary lines, either private, municipal, or State, and, as a consequence, are occasionally found in jurisdictions to which they are not native, and even sometimes in adjoining States.

Since odors may be disagreeable, or offensive, or sometimes even seriously injurious to persons or property interests, they are frequently proper subjects for repression and abatement. When the occurrence of odors becomes serious enough to be a violation of law, whether common or statutory, that law may be invoked to repress those odors. Such legal repression or abatement is not always a simple or easy matter, even when the injury is suffered in the same legal jurisdiction as that in which the odors originate, but when the cause and the effect lie in different legal jurisdictions, and especially in different States, the problem of abatement is a still more serious one. It is not easy to reach across a State line and repress an odor.

Two instances will be cited where odors in their travels have ventured across State lines and have been abated by legal measures; in the first, by the legal remedies constitutionally provided and usually followed in such cases; in the second by creating, under what were rather unusual conditions, a novel form of legal relief, more expeditious and apparently as satisfactory in results as the usual form.

The first case is that of the fumes from the plants of two copper smelting companies at Ducktown, Polk County, Tenn., near the southern border of the State, which fumes were the cause of serious injury to property interests across the line in the State of Georgia.

The efforts of the injured parties to obtain relief by private litigation proved unsuccessful, and the State of Georgia finally sponsored the cause of its citizens who had suffered injury and, in October, 1905, brought an action for injunction against the two corporations in Tennessee responsible for the production of the injurious fumes, which, having destroyed all vegetation in sight in Tennessee, crossed over into Georgia and caused the injury to vegetation and animal life there complained of.

The defendant corporations were the Tennessee Copper Company and the Ducktown Sulphur, Copper, and Iron Company. As one of the parties to the litigation was a sovereign State, the case was necessarily brought as an original action in equity before the United States Supreme Court.

The Tennessee Copper Company's plant is about ½ mile from the Tennessee-Georgia line, and the Ducktown Sulphur, Copper, and Iron Company's plant is about 2½ miles from that line. The injuries suffered were from large volumes of sulphur dioxide discharged by both plants, originally from the ground-roasting of the ore, and, later, from the smelting furnace chimneys.

The copper ore used by both companies was a mixture of pyrrhotite and chalcopyrite carrying slightly less than 2% of copper and about 20% of sulphur. The Tennessee Company used about 450 000 tons of this ore per annum, and the Ducktown Company about 200 000 tons, and prior to the filing of the action, the two defendants probably discharged into the atmosphere about 240 tons of sulphur per day.

Like all original actions before the U. S. Supreme Court, testimony was taken before a commissioner, the hearings were widely separated and long drawn out, and at irregular intervals the Court itself heard motions, made rulings, delivered opinions, and, finally, in the case of the Ducktown Company, issued a decree granting a partial injunction which required the company to restrict the discharge of gases to the equivalent of 20 tons of sulphur per day during the growing season from April 10th to October 1st of each year, and to 40 tons per day during the remainder of the year.

In the case of the Tennessee Copper Company, the Court recognized a stipulation entered into with the State of Georgia, by which the State of Georgia agreed to refrain from asking a decree of injunction prior to October, 1916, on condition that the Copper Company would: (*a*) provide a fund annually to compensate injured parties in Georgia; (*b*) conduct its plant subject to inspection in specified ways; and (*c*) between April 10th and October 1st of each year limit the smelting of green ore to such quantities that the sulphur dioxide therefrom could be taken care of by its sulphuric acid plant when working at its normal full capacity. This arrangement between the State of Georgia and the Tennessee Copper Company still continues, and the case before the Court is continued indefinitely, no decree having ever been issued against this defendant. The awards of damages to Georgia claimants, the administration of the indemnity fund, and the compliance generally with the terms of the stipulation, are determined by a permanent commission of three members, of which one is chosen by the Tennessee Copper Company, and one member and an arbitrator or umpire by the State of Georgia.

During the past three years the defendant Ducktown Company has also been permitted by the Court to operate under this same stipulation conjointly with the Tennessee Copper Company. Each of the two defendants contributes annually to the indemnity fund a fixed proportion of the total awards made.

Thus, after many years spent in litigation before the U. S. Supreme Court, without including the previous period of litigation as private individuals, a reasonably satisfactory adjustment was finally reached.

The second instance cited of inter-state odors is that which Mr. Tribus simply refers to, namely, the case of the West End Association and the City of New York, Plaintiffs, *versus* The Barrett Company of West Virginia, The Corn Products Company, The General Chemical Company, The Midland Linseed Products Company, The Valvoline Oil Company, The Bulls Ferry Chemical Company, and Spencer Kellogg and Sons, Defendants.

This case is cited solely because of the very novel and original form of legal remedy invoked. During and before 1916, the defendant corporations which had manufacturing plants at or near Edgewater, N. J., on the west bank of the Hudson River opposite West 80th Street to West 110th Street, New York City, were, or at least some of them were, producing at their New Jersey plants offensive odors. These odors were blown across the Hudson River and greatly annoyed the citizens of New York City living on or near the east bank of the river opposite the plants in question. An action had previously been brought in 1915 by the Attorney General, representing the

State of New York, before the U. S. Supreme Court for an injunction to restrain the offending New Jersey corporations from discharging the objectionable odors. Beyond having some investigations made by the State of New York, the case was never prosecuted and still lies dormant. A strong local civic organization called the West End Association being already active in the locality affected by the fumes, took up the matter for the citizens. Instead of resorting to the usual litigation, either as private plaintiffs before the Federal District Court, or through the case already brought by the State of New York as plaintiff before the U. S. Supreme Court, as was done in the Georgia-Tennessee copper case cited, and in the New York *versus* New Jersey Bayonne fumes case, also referred to by Mr. Tribus, the West End Association developed the following form of relief.

An Act of the New York Legislature was procured, being Chapter 292 of the Laws of 1917, amending the general corporation law which constitutes Chapter 23 of the New York Consolidated Laws. This amendment, which became Article 9-A of the General Corporation Law, provides in Section 200:

"That any domestic or foreign corporation which shall so conduct its business without the State by the emission or discharge of dust, smoke, gas, steam, or offensive, noisome or noxious odors or fumes, so as to unreasonably injure or endanger the health or safety in this State [New York] of any considerable number of the people of this State, shall be deemed guilty of a nuisance, and the charter of such corporation if incorporated, or formed by or under any law of this State shall be deemed forfeited in the manner prescribed in this Section, or its certificate of authority to do business in this State [New York] if incorporated or formed under the laws of any other State shall be declared revoked and annulled in the manner prescribed in this Section and in either case shall not be revived except as prescribed in the next Section."

The law also provides the following procedure: Complaints shall be made to the State Commissioner of Health. He shall cause a copy thereof to be served on the corporation complained of, requiring that the matters complained of be abated, or that the charges be answered in writing within a time specified. If the charges are not thus satisfied, and if there appear to be reasonable grounds therefor by the State Commissioner of Health, he shall cause such charges to be investigated and shall fix a time for a hearing on such complaints. If the State Commissioner of Health after hearing and investigation shall find that such corporation is conducting its business without the State so as to injure or endanger unreasonably the health or safety in this State of any considerable number of people of this State, he shall file his findings in duplicate with the Secretary of State and with the Attorney General. A certificate of the Secretary of State giving notice of the filing of such findings shall be served on the corporation if domestic, or on the designated agent of a foreign corporation authorized to do business in the State, and thereupon the charter of such domestic corporation, or the right of a foreign corporation to do business in the State shall be suspended for thirty days. If at the expiration of that period, the State Commissioner of Health shall on further investigation and hearing render a finding that the nuisance is continued, he shall cause a notice of such determination to be served on the corporation or the designated agent of a foreign corporation,

and published once a week for two successive weeks in the official State paper. On the tenth day of such service and publication, the charter of the said corporation if domestic, or the certificate of authority to do business in the State if a foreign corporation, shall be deemed to be forfeited.

Any person who shall attempt to exercise any powers under the charter or the certificate to do business, which has been so revoked or forfeited, shall be guilty of a misdemeanor. If the charter of a domestic corporation has been forfeited, the Attorney General shall apply to the Supreme Court for the appointment of a receiver of the property, who shall have all the powers and duties, as far as is practicable, which are prescribed by Articles 10-A and 11 of the General Corporation Law. The Act also provides for the reinstatement of a charter or of the authority to do business, after the nuisance has been discontinued, and after a suitable guaranty has been furnished that the corporation will not longer maintain such nuisance.

Equipped with this new form of legal relief, the two plaintiffs in this action, representing and acting for a large number of private individuals and, perhaps, some firms and corporations, who were suffering from the odors, commenced proceedings in the summer of 1917 against the defendant corporations under the new law before the New York State Commissioner of Health. Two separate investigations were instituted: The first by the plaintiffs to establish in some detail the facts on which to elaborate the charges, to establish the general feasibility of abatement, and to base the examination and cross-examination of witnesses; the second, later, by the State Commissioner of Health to supplement the testimony developed at the hearings, on which to predicate the findings. Under the first investigation, the inspection of the plants of the defendant corporations clearly showed that the occurrences of odors causing offense in New York City could be grouped into two distinct classes: (1) those resulting from the usual, normal operation of the several plants, which, while fairly constant in character and volume at the plants themselves, nevertheless produced widely varying degrees of offensiveness in New York City, depending on the direction and force of the wind, and on the humidity and temperature of the air; and (2) those resulting from the occasional (originally frequent) lapses from normal operation of the plants, due to carelessness, interruptions, changes, etc.

The results of the litigation have been generally favorable. No charters or certificates of authority to do business in New York State have been forfeited, or even suspended. The immediate effect of the commencement of the proceedings was to diminish very considerably the frequency and severity of the spasmodic or occasional odors of the second class. In addition, the defendant corporations which were the worst offenders, have made extensive efforts toward abatement by experimentally introducing various means of preventing, absorbing, and neutralizing the fumes which cause offense in New York City. The results of these efforts, which are still being continued, have even thus far been fairly effective.

The hearings and investigations by the State Commissioner of Health are still continued at infrequent intervals, mainly for the purpose of determining the progress in abatement accomplished by the defendant corporations at the

plants, and of giving them further time in which to perfect their improvements. The West End Association, as well as the City of New York, maintains a vigilant and stimulating watchfulness of all proceedings and developments, and as plaintiffs are represented of course by counsel at all hearings and conferences. Thus, sanitary science has acquired another legal weapon with which to combat the nuisances arising from "some inter-state odors".

This form of legal remedy for injuries caused within a State by extra-State corporations is believed to be novel, and the present case of the West End Association and New York City against the New Jersey corporations is the first brought under the new law of 1917. It would seem that, with proper State legislation, this remedy should be applicable in other States and to other inter-state wrongs than odor nuisances, namely, to the cases of the diversion, to the interruption of flow, or to the pollution, of streams flowing through or past one State into or past another State, except in the case of streams which are debarred from State jurisdiction by reason of their being Federally navigable or otherwise subject to Federal jurisdiction.

It is hardly necessary to point out that the efficacy of this form of remedy, as far as it relates to foreign corporations, depends entirely on the degree of importance which the erring foreign corporations attach to the privilege of doing business in the State of which the complainants are citizens.

ANDREW J. PROVOST,* JR., ESQ. (by letter).—The author has performed a real service in calling professional attention to the obstacles in the presentation before the Courts of specific, conclusive scientific evidence regarding odor nuisances.

In other nuisance evidence, such as relates to liquid wastes, the camera, volumetric measurement, laboratory analysis, etc., can be counted on to support and to lay the foundation for an expert opinion. In regard to the smoke nuisance, also, various supporting data are obtainable. On the questions of odors, however, the expert is unable to justify his opinion otherwise than by his sense of smell, which, to the Court, must appear little different from that of the lay witnesses.

If the expert could state that he was familiar with the process of the plant, the chemical combination of the gases discharged, and the constituents thereof which produce odors; that he had isolated from the atmosphere at certain distances from his plant odor-producing elements and had subjected these to analysis according to standard technique and had identified them as the same as those produced in the defendant's plant, and that he knew from observation and study that these elements are injurious or non-injurious, as the case may be, to the health and comfort of normal human beings, how different would be his position before the Courts. Possibly he will never be able to do this, but he can, perhaps, accomplish more for human comfort by working within the plant, by perfecting methods such as have been described by Professor Whipple, whereby the odors produced in the offensive trades will be absorbed, neutralized, or destroyed before reaching the atmosphere.

* New York City.

Some of the problems thus far studied would include: Garbage reduction works, slaughter-houses, piggeries, fish-rendering works, sewage treatment works, etc.

Garbage Reduction Works.—Many engineers began their experiences with the Barren Island plant, referred to by the author, and have appeared as friendly advisers or as hostile critics to its managers, at one time or another, during the past thirty years. It seems unlikely that another plant on such a scale will again be attempted and attentions and studies are directed to other types of plant, to better methods of operation, and to the evolution of more efficient operatives.

Slaughter-Houses.—The establishment of large abattoirs in the thickly populated centers, has resulted in intensified effort on the part of many operators to avoid the production and escape of odors. In some instances, chemicals which are quite effective in neutralizing certain peculiarly offensive odors, have been tried experimentally by the writer for the neutralization of other types of odors without much success.

Piggeries.—Offensive piggeries still exist, although it has been proven that the fault lies with the operator and not with the hogs. During the World War, many of the worst types of such plants were built, which defied regulation. Injunction proceedings were resorted to in some cases, but the general need for pork and the fact that the hogs consumed military camp garbage, secured immunity from successful prosecution.

Fish-Rendering Works.—Numerous large establishments exist, usually in quite isolated locations, for the extraction of oil from fish. The waste products consist of a slimy, liquid gurry and a comparatively dry scrap. The scrap is used as a fertilizer base and, if immediately treated with sulphuric acid to fix the ammonias, it is not particularly offensive, even if stored for considerable periods in large quantities. The gurry which cannot be discharged into streams without visible nuisance, is usually treated in tanks to precipitate the grosser organic solids. Fermentation results in an odor indescribably offensive. As the result of complaint and State action in some cases, condensers have been erected, which are effective in disposing of gurry wastes without the escape of odors and, at the same time, have conserved an appreciable part of the available nitrogen. A plant of this kind, which was threatened with an order to suspend operations, was modified by the writer to such an extent that complaint was withdrawn.

Sewage Treatment Works.—The cause for odors in and about a sewage treatment plant usually arises from ignorant, incompetent, or careless operation. There are, however, certain odor-producing processes which can be largely controlled by the designer. It is known that the odors which travel farthest and which cause the most complaint are produced by spraying the effluents from sedimentation tanks in the operation of open sprinkling filters and by the open lagooning or drying of sewage sludge. In certain cases of this kind, nuisance odors persist to distances as great as ½ mile or more. The writer has been able to control these odors so as practically to avoid all complaint, even in plants located in the midst of settled communities, by

housing the sprinkling filters and the sludge bed areas. The gases are then either re-absorbed by the effluent liquid or are discharged in such uniform, small quantities as to be substantially unappreciable.

Engineers who design apparatus for handling and disposing of offensive products and wastes are justified in demanding the highest efficiency in operation and regular supervision of the plant.

Odors travel usually in the direction of the wind and are frequently unnoticeable in other directions. In the absence of wind and vertical atmospheric currents, with a low barometer and with fog or mist, there appears to be a tendency for the odor-carrying gases or vapors to combine with the atmospheric moisture and to travel with it, close to the ground, until gradually released.

The plea made by the author for regulation of offensive trades by imposing restrictions on the installation of equipment and proposed methods of operation, instead of waiting to abate a nuisance after it is created, appears to be sound and deserves careful consideration.

Research along many lines is required before sufficient knowledge of handling putrefactive and fume-producing products is acquired to permit experts to go before the Courts and satisfy them beyond a reasonable doubt that as planned a certain project will or will not create a public nuisance.

In cases where the nuisance has been created, the Courts have held, as cited by W. H. Dittoe, M. Am. Soc. C. E., in his monograph, "How to Control Nuisances from Offensive Trades", that:

"It is no defense to an indictment for maintaining such a nuisance, that the business, trade, or occupation which occasions it is a useful one, or that it is really a public benefit, contributing largely to the enhancement of the wealth, prosperity, or commercial importance of the community, or that it furnishes, on the whole, a convenience to the public which more than counterbalances the detriment it occasions. For if it is in reality a nuisance or operates as such on the public, no measure of necessity, usefulness, or public benefit will afford a justification for maintaining it. Nor is it any defense to show that the business is carried on in the most prudent and careful manner possible; that the most approved appliances known to science have been adopted to prevent injury. The question of care is not an element in this class of wrongs; it is merely a question of results, and the fact that injurious results proceed from the business, under such circumstances, would have a tendency to show the business a nuisance *per se*, rather than to operate as an excuse or defense, and the Courts would feel compelled to say that, under such circumstances, the business is intolerable, except when so far removed from residences and places of business as to be beyond the power of visiting its ill results on individuals or the public."

No doubt there are special and unusual cases of odor nuisance which are entitled to a somewhat different viewpoint. The writer has in mind some experiences resulting from his service as sanitary expert during the construction of the Catskill Aqueduct. For a distance of about ten miles, this work ran through the Croton water-shed, which at that time was furnishing most of the water supply for the City of New York. Several thousand workmen were employed, most of whom were housed in regulated labor camps. When it was contemplated to commence this part of the work, the decision was reached that all human wastes must be kept from the streams and water-

courses and that the most effective means would be secured by incineration. Removable, water-tight receptacles were provided for the entire line of the work. These were collected daily and their contents burned in various types of furnaces. The strange, original character of odor produced was at the first experience quite startling. The gases, due to their high temperatures, were very volatile and were most noticeable at considerable distances and usually on higher ground. By carefully selecting the sites of the furnaces, it was generally possible to minimize the odor nuisance, and although the practice of night soil incineration was largely extended to the other sections of the work, throughout a length of about 100 miles, very little complaint was made. Possibly, this was because people felt the annoyance was only temporary and that its presence was justified largely by the necessity of safeguarding the sanitary condition of the streams.

Had the complaints been more numerous and severe, it is quite possible that means might have been provided for reducing the odors by smoke consumers of suitable type. During the five years' occupancy of the Croton watershed not a case of typhoid developed among the force employed, nor at any time was there any suggestion made that the sanitary quality of the water supply of the city had been impaired.

If injunction had been sought against the odors from these incinerators, it appears highly probable that neither the Courts nor any expert board would have felt that the alleged discomfort caused by their operation was paramount to the necessity of safe-guarding the water supply of a great city.

Garbage and other putrefactive organic wastes must of necessity be destroyed in the most rapid manner practicable, and this necessity imposes the obligation to devise apparatus and methods of operation which will avoid, as far as possible, cause of offense and discomfort to individuals and the public.

ROBERT SPURR WESTON,* M. AM. SOC. C. E.—The speaker will confine himself to a discussion of three odors: First, those given off by sugar-house waste; second, those given off by wastes from the manufacture of lactic acid; and, third, those produced by oil refineries.

In the manufacture of sugar, cane juice is expressed; the water is evaporated from it in multiple effects and vacuum pans, and cane sugar is obtained from the concentrate by crystallization. The distillate which contains considerable sugar, is usually wasted, together with some organic matter and some press-cake water containing organic matter, including various gums and sugar. Cuban sugar operations are conducted in the dry season and the wastes are discharged into lagoons or dry arroyos. These wastes begin to ferment even before they leave the sugar-house, which results in a vile odor from the hydrogen sulphide mixed with acid and the organic compounds containing sulphur; there is no odor much more disagreeable. Starch factory waste is nearest in the odors given off; but most of the starch factories, are located in cooler climates, and the nuisance is not so great. Those who have been through Cuba have experienced this odor from sugar-house wastes,

* Cons. Engr. (Weston and Sampson), Boston, Mass.

and have noted the effect of the waste on the streams. The remedy for this odor lies in a better method of waste disposal, which has not yet been attained.

Lactic acid is made by hydrolyzing starch and fermenting the product. The principal source of starch is vegetable ivory, a dense tuber from Africa, which ferments, producing lactic acid. This acid soon accumulates, and inhibits the growth of the bacteria of fermentation. Fermentation starts again after lime is added. In a short time, the process reaches its limit, and the lime and organic matter are precipitated. The precipitate is removed by filtration, and the filtrate containing the lactic acid is concentrated in vacuum pans. If the various wastes from this process are discharged into a lagoon or a stream where dilution is insufficient, they ferment with the production of butyric and other organic acids, hydrogen sulphide, and also compounds of sulphur and organic matter. Between New York City and Boston, Mass., a plant was started during the World War, and continued until it was put out of operation in 1919 by the action of a town board of health. The odor from the untreated waste was observed at times 2½ miles away and white lead paint within a radius of ¼ mile was turned black by the sulphur gases given off.

During 1921, the speaker had to deal with the odors produced by oil refineries, which odors Mr. Gage has also described. The source of fuel oil, is crude petroleum, and refineries are using more and more Mexican oil which is rich in sulphur. This oil is split by distillation into fractions, the lighter fractions being kerosene and gasolene. A refinery sometimes produces lubricating oils, gas oils, fuel oil, and, in addition, the heavier products, such as paraffin, asphalt, and coke. For many generations, the people of Massachusetts have been accustomed to the odors produced by the drying of the descendants of the "sacred codfish"; but oil odors are new and terrifying. Not only were objections made to the odors from the newly constructed refineries, but the smoke produced by the burning of oil was also a cause of complaint. Coal furnaces which had been hastily altered to burn oil, frequently produced a sulphurous smoke, particularly on Monday morning when late firemen tried to make up for lost time. Where the vapors and smoke were uncontrolled, conditions became so that people closed their windows at night to shut out the bad smells, and cases of nausea and vomiting were common.

Economic conditions demanded oil for fuel, and more refineries were completed. Locations were often unwisely chosen, and neighboring districts were gassed until the residents rebelled. This intolerable condition resulted in a demand for the cessation of either the odor or of oil refining. Certain refineries have stopped odor production; others have been forbidden to perform certain offensive operations, such as making coke, etc.

The means taken by certain refineries to control the production of odors have not been successful, their failures having been due to poor engineering, and especially to poor management, rather than to inherent difficulties. The most successful plants have either put all the refining apparatus, including tanks, under a vacuum system, and have passed all the gases through a fire, or subjected them to treatment by washing with some of the raw material going through the process; that is, the counter-current principle has been

applied by washing the distilled gases with the raw material about to be distilled.

The washing of gases in water simply transfers the odors to the water which has at least as much tendency to give off gases to the air as the oil itself, and very often the discharged wash water simply transfers the odor to another location.

In observing an odor-producing plant, the first effort should be to make the adjectives which have been used so generally to describe odors, to mean something. One way of doing this is to have the smelling systematic, that is, locate the odors from the leeward side of the plant, in order to determine the distance an odor can be detected under various air conditions. By plotting the observations day after day, one can obtain a graphical representation of the characteristics of any plant for odor production.

In order to make the record of one gas more complete, the speaker's firm, with the aid of the Wallace and Tiernan Company, Incorporated, adapted what is known as the Palmer dust apparatus for measuring the hydrogen sulphide in the air. The method was more delicate than the human nose, which, ordinarily, was able to detect about 1 part of hydrogen sulphide in 10 000 000 parts of air. This is a low concentration, but with the apparatus referred to, as little as 15 parts of hydrogen sulphide in 1 000 000 000 parts of air could be detected or about one-eight of the quantity which the observers could smell.

This Palmer spraying apparatus is really a nebulizer, which absorbs gases passed through a nebulized absorbent. It consists of a U-tube with a condenser, through which air is drawn by a fan and connected with the fan is a Venturi meter. It was customary to draw 100 liters of air through this device in 4 min.; 100 liters is about equal to ½ bbl., so that a considerable sample of air was tested at one time. By having three assistants cover the 24-hour period, an accurate record of the hydrogen sulphide content was made. In the tests, 35 cu. cm. of $\frac{\text{Normal}}{10}$ caustic soda was put in the U-tube. The air was then drawn through the liquid which nebulized and absorbed the gas. The caustic soda solution was then washed out of the U-tube and the hydrogen sulphide determined by titration with $\frac{\text{Normal}}{1\,000}$ iodine solution, using starch for an indicator.

This apparatus was tested thoroughly, and it was found that it would absorb all the hydrogen sulphide from the air passed through it and also any sulphur dioxide. Furthermore, it had an accuracy of $\pm$ 15 parts in 1 000 000 000.

It is well that engineers are attacking this odor problem. Sanitary engineering was a combination of bacteriology, chemistry, climatology, hygiene, and civil engineering. This new work which the speaker hopes will not be given a new engineering name, includes also meteorology, physics, and chemical engineering. The concentration of population and the rising esthetic standards will make work for engineers in these new fields.

ALEXANDER POTTER,* ASSOC. M. AM. SOC. C. E.—A few years ago, the speaker was asked to investigate the existence of odors in certain sewers. In the course of the investigation, the question of the travel of odors through sewers was studied and some interesting results were obtained both as to their direction and rate of travel. It was found that offensive odors were given off thousands of feet down stream from the point of emanation.

About twenty years ago, the speaker constructed a system of trunk sewers for a number of municipalities in New Jersey, including portions of the Cities of Elizabeth, Newark, Summit, Irvington, South Orange, West Orange, Millburn, and other places. During the construction of this system of trunk sewers, he also had supervision of the construction of most of the lateral systems within the confines of the various municipalities. Flush tanks were recommended and constructed throughout most of the lateral systems, but the main house-trap was omitted through most of the district, ventilation taking place through the house-risers.

In only one municipality did the local health authorities insist on the use of the house-trap, but, in order to economize on water, flush tanks were not put in service, dependence for flushing being placed on the use of a hose stream in the upper end of the sewers. As often happens under such conditions, the sewers were not flushed for weeks and months at a time.

Although the conditions as to capacity, flows, grades, and velocities were similar throughout the entire district, complaints were made from time to time about odors along the Joint Trunk Sewer through this municipality, which was built at joint expense to provide sewerage facilities for certain outlying districts. Repeated examinations of the Joint Trunk Sewer disclosed nothing that would justify the conclusion that the odors in this section of the trunk sewer had their origin therein.

The speaker's contention was that the odors were caused by unsanitary conditions of the lateral sewers, from which odors found their way down grade into the Joint Trunk Sewer. The air space above the flowing sewage in the Joint Trunk Sewer was proportionately very much less than the combined air space in the many contributing laterals; therefore, as the foul air found its way down stream to the Joint Trunk Sewer, it was forced out through the manholes, the quantity fluctuating with the volume of sewage during the different hours of the day.

It is a popular belief that the direction of the flow of sewer air is up hill. Experiments were made to substantiate the theory that the flow was down hill. At certain points along the Joint Trunk Sewer and the lateral sewers, smoke balls were introduced and the direction of the smoke was noted. The velocity of the smoke and its volume passing down the sewer, together with the velocity of the flow of the sewage, are indicated in Table 3.

The speaker believes that the controlling factor in directing the flow of the air down stream is the motion imparted by friction with the flowing sewage. Down-stream components are thus produced sufficient to carry the air in the direction opposite to that which might reasonably be expected.

* Cons. Engr., New York City.

Table 3 records velocities as high as 2.38 ft. per sec., which were sustained for distances of ½ mile in certain sections of the sewer.

TABLE 3.—SUMMARY OF EXPERIMENTS TO DETERMINE MOVEMENT OF AIR IN SEWERS, OCTOBER, 1916.

No. of experiments.	SEWER:		AVERAGE VELOCITY:		Ratio, in percentage.	Movement of air, down stream, in cubic feet per day.
	Size, in inches.	Grade, per hundred.	Sewage, in feet per second.	Air movement, in feet per second.		
1	8	1.9	1.6	0.32	20	20 800

10	15	0.40	1.82	0.29	16	26 800

*Main line only.

As a result of these experiments, the speaker not only succeeded in having the sewers cleaned more frequently, but also had the traps eliminated so that gases forming in the sewers were freely vented to the atmosphere at each house connection, and thus the nuisance was abated.

CALEB MILLS SAVILLE,* M. AM. SOC. C. E. (by letter).—As a boy, the writer well remembers the smell and the choking sensation, experienced at night, when a strong east wind blew up the river valley in which his home was located. This wind was followed in the morning by a yellow haze, which left a dark discoloration on the houses in the lower part of the town.

The conditions producing the odor mentioned were due to emanations from a chemical manufacturing plant about 4 miles to the east, of which sulphur products were the principal industry.

Subsequently, in another city, a large gas plant belched out its fumes at night to such an extent that it was impossible to sleep, at a distance of 4 or 5 miles away, on certain nights when wind and other atmospheric conditions were in conjunction. Happily for the inhabitants who are obliged to live in these places, both these nuisances no longer exist. Their disappearance, however, was not due so much to the regard of the plant directors for the comfort of the neighboring communities, as it was to the results of experimentation and advance in chemical science, which results indicated that valuable products were being wasted. Perhaps, a solution of the problem of community preservation from nauseating odors, would be to put industrial chemists at work to find a process which will dangle the lure of the dollar before the eyes of the plant manager. The possibility of such attainment might cause him to seek eagerly to conserve his filthy smells in order to exchange their cause for money. Possibly, we have not yet advanced far enough along scientific lines to cope successfully with many stages of this subject, and it may be that later developments will disclose the fact that all these odors are as yet

* Mgr. and Chf. Engr., Board of Water Commrs., Hartford, Conn.

unrecognized indications of a present waste which, when properly treated and conserved, will yield products too valuable to be overlooked. For example, it was only a comparatively short time ago that the gases of combustion were wasted, yet, although people were susceptible to the coal-gas smell which was more or less noisome to some, it was not recognized until recently what waste was going on in unconsumed fuel.

The author remarks on the hopelessness of attempts at the mathematical measurement of odors and rightly mentions the disagreement as to the character and intensity of the same odor. Although this is true, as applied to those who are untrained, it is equally true that the organs of taste and smell are susceptible of marvellous development. The practical agreement of several trained observers as to the intensity of odor of a water and the almost uncanny unanimity of opinion of several tasters of coffee, tea, and spice is sufficient indication of what it is possible to attain.

In this connection, also, the writer would like to call attention to the unique and valuable work of George C. Whipple, M. Am. Soc. C. E., in classifying the comparatively faint odors of potable water. On page 18 of his book on the "Value of Pure Water", Professor Whipple gives a diagram from which he says "one may calculate what may be called the esthetic deficiency of water". The curves of this diagram are built up "by adding together the percentages of objecting consumers", 100% being an odor to which everybody would object. In his discussion, Professor Whipple recognizes the difficulties of classifying odors and gives three separate equations for satisfying as many conditions.

Although these curves relate, as stated, to the comparatively faint odors of a potable water supply, it may be that a similar classification can be worked out for the odors of various industries. After some study, a scale may be arrived at, whereby it will be practicable to make more definite statements as to the probable number of people in the area exposed, who will be affected seriously by a certain odor, and thus decide whether or not the odor is a nuisance. It is well known that some persons are especially sensitive even to slight odors; however, if only a small percentage of the whole number are affected, the condition could hardly be called a public nuisance and a subject for drastic action.

Whatever conclusions are arrived at, in any individual case, it must be recognized that the solution of the problem lies in a proper balance of many conflicting elements, and that, very likely, the matter may resolve itself into a decision as to the degree of odor permissible rather than total elimination. The standard probably would be based on the reasonable use of the air, the possibilities of practical remedial action, and the economic value of odor elimination, as opposed to air pollution by the discharge of noxious or ill-smelling vapors.

Proceeding along this, or a similar, line, it would seem that after a time a sufficient number of precedents would be established, so that it would be possible with some degree of certainty to bring forward such evidence of polluted air and its results, as affecting persons and property, that the Courts would be willing to apply measures for relief. For this purpose, however,

trained observers are required, for the ordinary individual is incapable of differentiating as to intensity of odor and, indeed, it is probable that a large proportion of the people of a community are unable, quickly, to determine whether it is taste or smell which offends them.

Proceeding along the lines which have been suggested, it is probable that a valuation curve, or rather one of depreciation could be worked out similar to Professor Whipple's valuation of attractive water, from which the financial loss to a community, as well as the personal annoyance of the inhabitants, could be determined. Such evidence, if it were available, would be much more effective in abating a nuisance than many individual complaints of a more or less indefinite nature, which when investigated often become of little value, because of differences in the personal equation of the observer.

In general, the matter of elimination of disagreeable odors seems to be strictly analogous to the pollution of natural watercourses into which sewage and waste are discharged by the method of disposal by dilution. Some of the methods found to be helpful in correcting unbearable conditions in regard to water pollution may, perhaps, be useful in dealing with the pollution of the air.

GEORGE A. SOPER,* M. AM. SOC. C. E. (by letter).—The author has presented another question, which affects life and comfort intimately and continually and on which there is a deplorable lack of information. It is surprising to note the number of these questions, and it is well for engineers to discuss them. Such discussions may not always advance the subject very far, but they, at least, bring together many of the more firmly established facts concerning it, and are likely to indicate the directions in which more practical information is needed.

The basis on which the paper is presented is interesting. A great deal of scientific discussion could have been abstracted from encyclopædias and other sources, but the author seems purposely to have avoided this form of exposition and to have directed his inquiries to the observations of engineers, apparently in the hope of obtaining first-hand information on a number of specific subjects which he has carefully stated.

The paper was written in a more or less humorous vein, for in no other way can the title and some of the theories which have been put forward be so well explained. It is, of course, as well known to the author as to any one that odors do not have "habits", that they do not in strictness "travel", that there are no such things as "smell atoms" and that to seek to kill one odor with another is almost always bad sanitary practice. This procedure has been extensively practiced, especially with toilets, with the result of tainting the air of hotels, theaters, and clubs and rendering the presence of ill-kept water-closets unduly noticeable in subways, railroad stations, and boats. It is hoped that this practice will not be attempted, on a large scale, out of doors. The general atmosphere is a large space, as the writer once found when he was called on to get rid of the odor produced by the fermentation of more than 100 000 bushels of wheat, which had been water-soaked in a flood and, later, exposed to a hot sun.

* Cons. Engr., New York City.

The subject which the author states he particularly wants discussed is the distance from sewage and garbage plants to which an offensive odor may travel and cause serious annoyance. A brief and direct answer to this question cannot be made. The subject is too indefinite; nothing is fixed about the problem. Every element in it is variable. In a general way, it may be said that odors will not travel far unless under exceptional circumstances as to the quantity of the odorous substance and favorable states of the atmosphere; but this statement lacks the very precision which is desirable.

Before much progress can be made toward definiteness, it will be necessary to define the terms used. It must be agreed as to what shall be meant by the word "offensive", and the word "annoyance" must be defined. These words are difficult to define, as they represent mental states which, in turn, are produced by sensations. They are reactions which result from reactions. They are subtle and are likely to be affected by conditions which cannot be discovered to have any necessary connection with the problem. The final effect which may result from the operation of a set of known conditions at one time, may be different from the effect which the same conditions may appear to produce at another time.

For these reasons, that which is disagreeable to one person may not be so to another; that which is unpleasant on one occasion may not be so on another. It often happens that a person at first objects to an odor to which he later becomes indifferent; and he may become actually fond of it in time. The odor of cheese affords an example; tobacco smoke is probably another. People are not fond of these odors at first, however much they may like them later. It is not the odor, but what it suggests, which is the important thing.

If the odor suggests the existence of something which is dangerous, much more objection will be made to it than if no alarming association is aroused. The element of danger, however, need not be greatly in evidence. Odors may suggest conditions that are disturbing to one's sense of comfort, of well-being, and when this sensation results, the objection raised may be emphatic. As regards emphasis, it is well to remember that some persons by temperament, speak loudly, although only slightly annoyed, whereas others are truly long-suffering. In other words, the annoyance produced is not to be measured by the noise which is made about it.

There is little doubt that physiological actions are stimulated by odors, and it often happens that these are not only not within one's control, but they may be beyond one's knowledge. It seems reasonable to suppose that a hospital placed in an agreeable pine forest may have a different effect on its patients than one located in a malodorous part of a city; and what is true of people out of health in this case may apply in lesser degree to those whose health is normal. It is fair to suppose that the manifold unfavorable conditions of city life, among which odors occupy no inconspicuous place, have a decided influence on most of the people who encounter them. Cities are by no means the healthy places which some have been led to suppose.

The late Professor William T. Sedgwick used to tell a story to illustrate the fact that even strongly disagreeable odors may seem pleasant and beneficial according to one's idea of their composition, origin, and effects. The school

teachers of Massachusetts were accustomed to meet in annual convention during the summers in the City of Boston. A feature of these annual gatherings was a trip on the harbor, with a stop for dinner at one of the shore resorts and an hour or so of leisure on the rocks. On these excursions, Dr. Sedgwick would say, the little schoolmistresses would be fairly exalted by the odors greeting them from the sea. They would climb down to water's edge, fill their lungs with long draughts of air and delightedly pronounce the magic word "ozone". "But", Professor Sedgwick would conclude, "You and I know that what they smelled was rotting sea weed. If they had known what caused the smell, they would have fled the place, and lost the benefit which the air and their ideas of the fresh sea breeze were giving them."

It is hoped that, for the benefit of sanitary science, further study will make the detection, measurement, and recording of odors more definite than it is to-day, but it seems too much to expect that the time will ever come when this subject will be put on the more satisfactory basis which exists with respect to the evidence of some of the other senses.

The odors from certain gases, dusts of various composition, and vapors of known chemical composition can be investigated with an approach to definiteness, but even when the amount of the irritating substance present in a given volume of air is known, no great progress will be made until the reaction of the average person toward the odor can be ascertained. To procure this information may not be possible, but it is a line of effort which certainly is worth further study.

This method of research was not considered practicable by the writer in his studies of subway odors.* The odors were mixed, as is often the case in practical problems. They were of various kinds, and for a long time their sources were in doubt. It was not until experiments were made to duplicate them, that the origins of the odors could be found. Briefly, these sources included the trap-rock of which the roadbed was composed, the hot brake-shoes, the lubricating oil, which was lavishly used when the road was first opened, the cement, which was used to fasten the tiles in place at the stations, and the great quantity of iron dust, which was produced in the operation of the cars.

It may be worth while to call attention to the fact that no relation exists between the offensiveness, or suggestiveness, of an odor and the distance to which it may be carried. For example, the River Thames at times is odorous from sewage throughout a distance of 25 miles below London Bridge, yet the smell does not travel far beyond the river banks. The East River, Harlem River, and Hudson River, at places, are very offensive, but it is only on particular occasions, fortunately not frequent as yet, that smells are carried more than a few hundred feet inland. It is reasonable to suppose that the malodorous zone will increase in time, if the harbor continues to be neglected, until the region about the shores will be continuously affected; but the waterways themselves will be highly offensive before a great deal of the smell is carried far toward the center of the city.

* "The Air and Ventilation of Subways", Wiley & Sons, N. Y., 1908.

There are frequent times, when the greasy smell of sewage is noticeable along miles of the Manhattan water-front. It is frequently detectable over a large part of Riverside Park and on the drive which borders the eastern limit of the Park; and it is unpleasant in some of the other parks which border on the harbor. Some of the recreation piers have sewers discharging directly under them, and the odors which assail the thousands of visitors at the times when these breathing places are most needed, are nauseating to those who have not become accustomed to them. In all these cases, however, the odors do not travel far. They annoy a great many people, not because they are carried a long way to the places where they are noticed, but because the people go where the smells originate. They go there to get fresh air and to enjoy the provisions the city has made for their health and enjoyment. By thus discharging the sewage, the city does much to destroy the attractiveness of these places which it has provided for the public welfare.

An incident has recently come to the writer's attention which shows that the odors of sewage are sometimes carried more than 1 000 ft. inland from the polluted waters which surround Manhattan Island. One night in the summer of 1921 a resident of East 86th Street was awakened by an odor which at first seemed to be due to an escaping gas jet. On opening the window, the smell became stronger, and it was observed that windows on the opposite side of the street were being raised by persons whose sleep apparently had also been disturbed, and people collected on the sidewalk to discuss the situation and decide what, if anything, was to be done. Investigation showed that the smell came from the East River, being carried by a gentle breeze. The night was warm and damp; the tide was low. The odor was uncommonly strong, which may account for the fact that its cause was not at first generally recognized. In some neighborhoods, the smell of sewage from the East River is of considerable interest, for it is said to furnish the citizens with a means of foretelling the approach of a storm.

Surgeon General Sternberg used to say that disagreeable odors should be interpreted as danger signals, for although they are unreliable guides if followed blindly, they are capable of doing great service in suggesting conditions which ought to be investigated.

Louis L. Tribus,* M. Am. Soc. C. E. (by letter).—The discussions confirm the writer's opinion, that only through the development of trained observers working along the same lines can intelligent classification be reached and anything approaching mathematical precision be attained.

The writer did not attempt any real definition of what constitutes differences between offensive and agreeable odors, or between those that may be harmful and those that are benign. He merely sought to outline the subject to which others might add data and from which, with later additions, helpful facts and conclusions might be taken. The results have warranted the hope.

Mr. Hansen enlarges on the point that certain industries must be considered essential, and thus be tolerated, while all effort should be made to cure the attending evils; also, that odors are most apt to be the barometer by

* Cons. Engr. (Tribus and Massa), New York City.

which the public rates them. He offers zoning as one of the means of relief, but not as a cure.

Professor Whipple discusses interestingly, the personnel of odors themselves and treats the subject along the following logical lines: (1) Physiology; (2) relation to health; (3) meteorological factors of travel; (4) governmental control; and (5) prevention.

Temperature has quite an influence, due to volatilization of the odor elements, and humidity plays an important part; and those discussing the paper naturally mention wind movement as the important element in dissemination.

Professor Whipple calls attention to the fact that frequently odors are an indication of unwholesome conditions, but that unwholesome conditions must not always be thought to be absent when definite odors are not present—carbon-monoxide is virtually odorless, yet very deadly, and is given off in large quantities during the combustion of most fuels. Governmental control cannot well step in until nuisance exists or can be clearly anticipated; and such control then should be handled with great circumspection, yet as the writer suggested, and to which others have agreed, it might be secured in part by intelligent official advice, prior to the act.

Prevention is a field for intensive study, and is one that has occupied the attention of many a factory chemist, spurred in some instances by public sentiment and wrath, but often by the earnest desire of the plant management to do better things.

Mr. Gage tells of some interesting observations in attempts to control the offensive odors from certain oil refineries in Rhode Island, the presence of which was greatly desired as helpful industries, yet the operations of which were not the most agreeable. The fact was brought out that, in these cases, hydrogen sulphide and other sulphide gases were the chief offenders, the Mexican oil that was used containing more than 4% of sulphur.

It is difficult to realize the enormous quantities of these gases, certainly not helpful and highly odoriferous, that are given off daily in refining the much needed oil.

Mr. Osborn, out of his long experience in the study of the design, construction, and operation of garbage works, corrects the writer in certain references to garbage plants, and is probably justified in so doing. He devotes most of his discussion to the action of garbage reduction works and the causes of the dissemination of their odors, which he admits are offensive when not controlled.

The point which he emphasizes as of greatest importance, is not so much how far odors do or can travel, but how can they be prevented from traveling, a most pertinent conclusion.

Mr. Hering gives some physiological facts as to the perception of odors and their neutralization; that liquids make good carriers and that careful study makes possible almost complete elimination in cases of refuse disposal and sewage works.

Professor Landreth has given quite complete data on certain interstate litigation of prime importance, and New York legislation that has recently

been helpful in abating certain undoubted nuisance cases, where odors of offensive character affected humanity and property at great distances.

Mr. Provost emphasizes some of the difficulties in the way of expert testimony and discusses certain specific types of offensive works, where publicity and, in some instances, drastic action, has secured the abatement of the nuisance, and also where a temporary nature has permitted operations, when permanence would have demanded cessation or change.

Mr. Weston discusses particularly the odors from sugar-house wastes, manufacture of lactic acid, and oil refining, and gives enlightening description of the processes and of testing apparatus designed especially to detect and standardize the odors given off, so as to make records that should be comparable and intelligible.

Mr. Potter contributes certain air-movement tests in sewers, looking to acquisition of knowledge as to the occurrence and behavior of sewer gases.

Mr. Saville rather looks forward to such scientific study, that curves and scales may yet be developed, that will enable far greater approximation of effects under standardized conditions, so that trained observers may even present data, that will be reasonably conclusive to the Court.

Dr. Soper emphasizes, as did the writer, the intangibility of odors; that some which at first might be offensive, later become tolerated; that offensiveness may not prove real danger, but should be a notice to take warning; that they have no fixed "habits of travel"; and gives from his experience in research, particularly in New York's subways and in its harbor, some interesting items.

In general, it is agreed that a study of odors and their habits of travel would be of great economic service, and that on the engineer, devolves that duty.

The writer feels justified in having brought forward the topic, believing that, from it, more of helpful facts will be gathered and promulgated for the betterment of general living and, perhaps, the pocket-books of engineers.

STREAM POLLUTION AND SEWAGE DISPOSAL*

A SYMPOSIUM

BY MESSRS. GEORGE T. HAMMOND, KENNETH ALLEN, JOHN F. SKINNER, W. L. STEVENSON, EARLE B. PHELPS, T. CHALKLEY HATTON, LANGDON PEARSE, AND W. H. DITTOE.

WITH DISCUSSION BY MESSRS. HARRISON P. EDDY, J. FREDERICK JACKSON, F. A. DALLYN, W. F. WELLS, ALEXANDER POTTER, EDWARD S. RANKIN, S. JOHN SCACCIAFERRO, GLENN D. HOLMES, RUDOLPH HERING, C. M. BAKER, P. H. NORCROSS, LEONARD S. DOTEN, JOHN A. GRIFFIN, AND CLARENCE E. KEEFER.

* Presented at the meeting of November 16th, 1921.

TANKS AND FINE SCREENS FOR TREATING SEWAGE

By George T. Hammond,* M. Am. Soc. C. E.

In considering the title of this Symposium, "Stream Pollution and Sewage Disposal", and what should be said about tanks and fine screens, the speaker's first thought was that perhaps the title should have been "Sewage Disposal and Stream Pollution", for observation of actual conditions rather tends to justify the statement often made, that sewage disposal is the main cause of stream pollution; this is sometimes the case even where treatment plants have been established. Not to mention instances known to most engineers, in which sewage is "disposed of" without any attempt at treatment, examples of American idealism and carelessness in sanitary works are sometimes found, in which elaborate and costly plants are constructed, and do not function because of ignorance or neglect on the part of those whose duty it is to care for their proper operation—sanitary engineering efforts conceived in faith, which, however, will not function on faith alone.

Engineers are familiar with the various forms of tanks of which quite a number are obsolete, and of fine screens that have been in use for many years in sewage treatment works, some of which are also obsolete. There has been an evolution from the ancient and odorous cesspool to the sedimentation and separate sludge digestion tanks of the present. Experience and experiments go far to prove that the latter afford the most satisfactory method of tank treatment, securing a high removal of suspended solids and complete digestion of the sludge, without much danger of a nuisance. Much experience with the design and operation, as well with overloading and abuse, of such tanks was gained during the World War, and the interested student can inform himself of many data from several important papers since published, of which the speaker will only mention the one presented by Leonard S. Doten,† M. Am. Soc. C. E., before the Society.

The speaker will not attempt any discussion of the various forms of tanks and fine screens so fully described in textbooks and so frequently seen in treatment plants abroad, but will confine himself to those which seem to have demonstrated their usefulness in ordinary American practice.

One of the latest extensive projects in sewage treatment is the proposed enlargement of the plant at Baltimore, Md., concerning which an interesting paper‡ has appeared recently. The following statement is quoted from that paper:

"Everything points to the adoption of sedimentation tanks in conjunction with sludge digestion tanks as the most logical solution of the problem for Baltimore conditions. None of the many troubles that have to be confronted in the operation of Imhoff tanks is found in treating sewage with sedimentation and sludge digestion tanks. No foaming is met with; no time is spent squeegeeing; no scum has to be removed; no skimming of tanks is required; and no uncertainties of operation have to be considered."

* Cons. Engr., Brooklyn, N. Y.

† *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919-20), p. 337.

‡ *Engineering News-Record*, Vol. 87, p. 654.

The experimental work on sewage treatment in Brooklyn, N. Y., extending over more than five years, appears to justify the conclusion reached in Baltimore as to the success of sedimentation and separate digestion, except that much difficulty was not found with the Imhoff tank.

The Imhoff tank affords a method of obtaining separate sludge digestion in a chamber placed under the sedimentation chamber. It eliminates the necessity of transferring the settled matter from one tank to another, and thus has an advantage over the separate tank system. That it has some unpleasant tendencies, however, must be admitted.

In the experimental work in Brooklyn, three Imhoff tanks were used, designated, respectively, as No. 1, No. 2, and No. 3. The capacities per day were as follows: No. 1, 150 000 gal.; No. 2, 100 000 gal.; and No. 3, 50 000 gal., each operating on a theoretic 2-hour retention period. The tanks were of different depths, but of the same plan, the cross-section at any proportional depth being identical in all of them. All the tanks were operated more than five years.

Among the points of interest observed during the Brooklyn experiments, the speaker will mention the following:

1.—For Imhoff tanks the sludge digestion capacity should be sufficient to carry the sludge for 8 months without discharging, and the capacity below the slots should be at least about 2 cu. ft. per capita for the population served. This large capacity not only is necessary for storage during non-drying periods, but it also appears to have some important relation to the digestive process, and helps to prevent foaming.

2.—Double slots, that is, one slot at the bottom of each inclined plane of the sedimentation chamber, with a triangular baffle beneath, instead of one plane passing under the other, appear to give the best results in these tanks and largely eliminate the need of squeegeeing the slopes.

3.—The slopes should be at least 1¼ vertical to 1 horizontal, and the flow should be parallel with the slopes and slots; a rate of flow equal to 1 ft. per min. is excellent.

4.—Scumboards and baffles add to tank efficiency.

5.—From observation, the speaker has reached the conclusion that two sludge digestion pockets under the sedimentation chambers are better than three, and that the best length for the sedimentation chamber would afford 60 ft. net for the flow between the scumboards at the inlet and the outlet. Provision should be made to reverse the flow.

During the World War, and while in the employ of the U. S. Government, among various assignments, the speaker was detailed to take care of the design of an Imhoff tank plant for Harriman Village and other industrial housing projects, and the City of Bristol, Pa., jointly. W. H. Boardman, Assoc. M. Am. Soc. C. E., of Philadelphia, Pa., was retained by the City of Bristol, and collaborated with the speaker on this work, which consisted of three Imhoff tank units, each of which had a capacity to care for 2 500 000 gal. per day of sewage flow, at a retention period of 1 hour, or 1 125 000 gal. per day at a period of 2 hours. The principles previously mentioned were carried out in the design of the plant, which has been in operation about three years and has given excellent service. There has been no trouble with the plant, no odors, and squeegeeing of the slopes is seldom required.

Many engineers have come to the conclusion that the Imhoff tank is an element of risk in a treatment plant. After having visited most of the larger and many of the smaller installations of this tank in the United States and abroad, the speaker's opinion is that to a considerable extent its bad name is due to faulty design, and, still more, to faulty operation.

Relative to the retention period in tanks: Experience and experimental work indicate that this period should be short, usually not more than 2 hours, even 1 hour will give the best results in many cases. Sedimentation is very rapid during the first hour and septic action may intervene during the second hour, and it is always desirable to keep the liquid part of the sewage as fresh as possible. Experimental results as well as observations tend to show that although not affording the high percentage of removal obtained by longer periods, a period of 2 hours gives all the preparation required for sprinkling filters or for direct discharge into a waterway affording sufficient dilution.

As tanks of all kinds have always given some trouble, even if such trouble is merely psychological, which must be taken into account, a method of mechanical removal of suspensa from sewage has long been sought. The fine screen is the principal result of this search and the advantages secured by apparatus of this type are many and obvious. Fine screens act on the sewage at once as it enters the plant, preserving its freshness, and do not foul the night flow. They may be used as the sole method of treatment where the effluent is discharged into a waterway which at all times has sufficient volume to provide the necessary dissolved oxygen to receive it. The same remark applies also to tank effluents of all kinds. Neither the fine screen nor the tank provides a complete treatment, and, in many cases, the use of either method must be followed by filtration. The tank will remove more suspensa from the sewage than the screen.

The problem of sewage treatment is mainly the separation of solids from liquids. Ordinarily, fine screens may be said to remove from 12% to about 30%—even higher in some cases—of the settleable solids. This quantity is considerably less than is removed by the tank, but the greater freshness of the effluent from the screen, and its freedom from probable nuisance in most cases, more than offsets the difference. Either tanks or fine screens will prepare sewage satisfactorily for application to sprinkling and other filters, as was shown by the Brooklyn experiments; therefore, either can be constructed as the advance guard of a future filtration plant.

There are many fine screen plants in operation in the United States, which are giving satisfaction as the sole method of treatment. One such plant may be seen at the foot of Dyckman Street in New York City, and there is another of the same type in Brooklyn, on which observations and experiments extending over four years have been made. More such screen plants are proposed and will probably be soon built, as they appear to give all the treatment conditions require for the present and for a long time in the future.

Attention should be called to the need of providing grit catchers and coarse screens ahead of the treatment plants; also, to the need of tide-gates and submerged outfalls, where necessary.

Other forms of tanks, not mentioned, are not at this time of importance in this connection. The old septic tank still has its use in some places, and is well known to the sanitarian as a friend or as a foe. Some special forms of tanks are of interest, such as the Travis tank, the Kreamer tank, the Dortmund tank, etc., but the results of their use have not proved them the best for stream protection, and none of them has met with much success under American conditions. The various forms of chemical precipitation tanks are being abandoned everywhere as unsatisfactory.

Where an effluent from a tank, or from a screen, is good enough under local conditions to be discharged into a waterway, it is important that it should be as fresh as possible, in order to insure against local nuisance, and that it should contain a minimum of bank-forming material which usually can be removed almost completely by a tank or with a screen of proper fineness.

The finely divided flocculent matter and colloid particles in suspension will make considerable inroads on the dissolved oxygen present, but if this is of sufficient volume and the floc remains in suspension, little, if any, harm need be anticipated. The solution of the problem depends on the oxygen demand created by the biological food supply present, and, in every case, local conditions should be studied by a competent biologist before the plant is designed.

Although separate sludge digestion tanks are now coming into considerable prominence, thus far there has not been much uniformity in their design, and much study and experiment are desirable to develop this form of tank. In some cases, duplicate settling tanks have been provided, as in some of the Dotea tanks, which are allowed to fill with sediment and sludge to the point of interference, and are then laid off for digestion, the other tank being used for sedimentation; and this method has met with success. Alvord has perfected a very interesting combination of settling and digesting tanks, but the field for improvement is still very wide in regard to this part of the subject.

In closing, attention may be drawn to the fact that many large cities which are not yet treating their sewage, are situated on waterways which for many years would afford ample supplies for disposal by dilution of a tank or fine screen effluent without further treatment, but which if contamination is permitted to go forward, will soon require far more costly forms of sewage treatment.

THE POLLUTION OF TIDAL HARBORS BY SEWAGE WITH ESPECIAL REFERENCE TO NEW YORK HARBOR

By Kenneth Allen,* M. Am. Soc. C. E.

Whether the waters are tidal or those of inland lakes, the fundamental considerations regarding harbor pollution are the same, but the effects are accentuated in sea-coast harbors for several reasons:

1.—The oscillations of the tidal flow alternate with periods of slack-water when solids settle rapidly to the bottom and form sludge banks.

2.—The presence of salt in the water tends to precipitate the soaps in the sewage, making the effluent noticeable by its milky appearance and promoting further sedimentation.

3.—Owing to the greater specific gravity of sea water, the warmer sewage rises rapidly to the top and spreads out in a thin layer, diminishing to a film of sleek which covers a large and readily distinguished area on the surface.

4.—As sludge deposits decompose, sulphureted hydrogen is formed in greater abundance in salt water than in fresh water, owing to the breaking down of the sulphates contained in the sea water. Sulphureted hydrogen is known as the most characteristic of the offensive odors of putrefaction.

In experiments made for the Metropolitan Sewerage Commission, the effect of salinity on buoyancy was well shown by releasing varnished croquet balls, weighted to a specific gravity of 1.000, at a given depth and noting the time of ascent. In a mixture containing 28% of sea water (specific gravity 1.007), the upward velocity was 3 in. per sec., while with a mixture containing 86% of sea water (specific gravity, 1.0215), this velocity was doubled.

The ascent of sewage from a submerged outlet would always be less than that of a solid ball, due to rapid diffusion forming a mixture constantly approximating in character the water of the stream. Therefore, the velocities mentioned may be taken as indicating the limiting maxima for sewage discharged in still water.

For the reasons stated, the discharge of sewage into salt water is very likely to be objectionable, particularly if it is discharged in a septic state, and, under otherwise similar conditions, more care is required for its proper disposal than in fresh water.

An excellent illustration is found in the discharge of nearly 100 000 000 gal. per day of septic sewage within a period of about 2 hours, about high tide, at Moon Island in Boston Harbor. This spreads rapidly over the surface so that several hundred acres of water have the appearance of undiluted sewage, although samples taken by the Metropolitan Sewerage Commission in 1911 indicated an abundance of dissolved oxygen at a depth of 1 ft. or more. In fresh water, diffusion would be much more general.

In the Borough of Manhattan, which to many is synonymous with New York City, the untreated sewage passes from about 180 outlets directly to the salt water of the surrounding streams. The result is that deposits form in the slips and under the piers so that dredging is necessary, and conditions offensive to the eye and nose result. This is also true of much of the Brooklyn and Bronx

* San. Engr., Office of Chf. Engr., Board of Estimate and Apportionment, New York City.

water-fronts, but conditions are better in the other less densely populated boroughs.

These unfortunate results of the present method of disposal could be largely avoided by the general introduction of fine screening, which is already being done at Dyckman Street, Manhattan, Hendrix Street, Brooklyn, and at the 43d Street, Oak Street, and Thirty-second Avenue outlets in the Borough of Queens. There would still be left in the water, however, a large part of the impurities in solution or in a finely divided state, making a continuous demand on the dissolved oxygen.

From 1909 to 1914, the depletion thus caused has been determined by the Metropolitan Sewerage Commission, Dr. G. A. Soper, M. Am. Soc. C. E., President, and, since then, by the Board of Estimate and Apportionment, New York City, Nelson P. Lewis, M. Am. Soc. C. E., and, more recently, Arthur S. Tuttle, M. Am. Soc. C. E., Chief Engineer.

The warm-weather record is interesting, as saturations are always high in winter. The most salient features are:

1.—The annual occurrence of total depletion for short periods in the Harlem River.

2.—The rapid decline in saturation in the Lower East River, reaching zero for the first time in September, 1921.

3.—The continued and general lowering of saturation in all the other main branches of the harbor, particularly at The Narrows, where a resultant of the depletion that has taken place in the Bay and rivers above may be noted.

It has been supposed that, although odors are not evolved as long as any supply of oxygen remains, they are likely to occur locally when channel saturations are less than 20 or 30 per cent.

Investigations have failed to support this view, as far as New York City is concerned, for during the past season a large part of the harbor has held less than these percentages of oxygen, without any resulting nuisance. Fish life, however, is undoubtedly interfered with, since it has been sufficiently well demonstrated that most edible varieties will not thrive where the percentage of saturation is under 30. The remedy for this phase of pollution lies in some form of tank treatment, by which most of the fine solids and some of the colloidal matter may be removed.

Large areas of the harbor covered with a film of oil may be mentioned as having caused much complaint recently. This condition has been prevalent along the Staten Island beaches and in the Lower East River, where it frequently extends practically from shore to shore. The cause is due in part to extensive oil works on Newtown Creek and at Bayonne, N. J., but more especially by the discharge of bilge water from incoming oil-burning steamers. It has injured the bathing beaches, increased the fire hazards, and interfered with fish life.

To summarize: The City of New York is discharging about 750 000 000 gal. of sewage daily into the harbor, mostly without any treatment. With the large tidal inflow of 12 700 000 000 cu. ft. of sea water at The Narrows and 4 700 000 000 cu. ft. from Long Island Sound twice a day, added to an average flow of upland water from the Hudson River of about 2 070 000 000 cu. ft. per

day, conditions such as obtained formerly at London, Glasgow, Naples, or Havana are not likely to occur soon here; but the rapid reduction of dissolved oxygen in the harbor is a danger signal which should not go unheeded.

Several important steps have been taken already to improve conditions: A number of intercepting sewers are, or soon will be, under contract, and within two or three years a number of modern fine-screening plants will be in operation. It is also hoped that a way will be found to provide a more thorough method of treatment for some of the more important outlets which are responsible for the polluted condition of the East and Harlem Rivers.

TREATMENT OF STORM-WATER

By John F. Skinner*, M. Am. Soc. C. E.

The sources of stream pollution commonly considered have been sewage and trade wastes. The discharge from storm-water sewers and from storm overflows on combined sewers is another element which in some cases may merit attention. Especially is this true when the stream is small, when it flows through built-up territory or a park, or when it is used for fishing or bathing, or the water is used for drinking by cattle or by man.

It has generally been considered that before sewage enters a stream it should be treated to remove:

(*a*) Heavy solids, grit;
(*b*) Floating and coarse suspended solids, screenings;
(*c*) One-half or more of the finer suspended solids, clarification;

and if the stream is small and sluggish so that insufficient dilution occurs:

(*d*) Oxidation of the effluent,

in order to avoid nuisance.

Economy usually dictates that the sewage treatment plant on a combined system shall receive only a part of the storm flow, while the remainder is discharged raw into the stream either at the plant or, as directly as possible, at convenient points along the main intercepting sewer, on the theory that, in time of storm flow, the dilution will be ample.

This is doubtless true if the stream is swollen at the time, for either the dilution is so great or such a load of other solids is washed in from the water-shed that the accession from the sewer is inappreciable.

However, if the storm-water discharge is due to a local shower, and the run-off from the water-shed of the stream is not generally augmented, the dilution may be reduced and the velocity may be so small that deposits will occur, the heavy material forming bars and the floating portions becoming entangled in the vegetation and littering the shores.

After a period of drought, when a sudden shower causes storm-water to debouch into the stream, the first flush carries the accumulated deposits from the sewers, accompanied by street refuse, followed by a greater dilution of rain water.

The discharge of storm-water being occasional, the finer suspended solids often may be oxidized without serious offense, or be carried on by the current if they are not entangled in other grosser deposit-forming materials. The treatment indicated for storm-water, therefore, is the removal of this coarse and heavy detritus before the effluent is admitted to the stream.

The heavy solids consist of grit, ashes, sand, gravel, bones, fruit pits, tin cans, rubber, leather, and objects in part made of metal, which deposits will settle in a current of 1 ft. per sec. If the larger objects are excluded by racks, the resulting deposit will be mainly grit, ashes, sand, and gravel.

The floating solids consist of wood, straw, leaves, fruit rinds, remains of fireworks, rubber, baseballs, and toys lost in the surface sewers. If racks

* Cons. Engr., The Dorr Company; Prin. Asst. to City Engr., Rochester, N. Y.

are provided they will accumulate, in addition to the last mentioned, a collection of the coarse heavy objects mentioned previously.

The material to be removed, therefore, may be classified as grit and screenings. Coarse racks with bars from 3 to 4 in. apart will generally precede the grit-chambers and the finer screenings will be removed later.

If the proposed detritus plant is at or near a sewage disposal plant where attendance is constant, racks may be raked at any time and will occupy the least space if placed vertical or slightly inclined. If the construction is in an isolated location where only periodic attendance is contemplated, the racks should be set on a flat incline, 3 or 4 horizontal to 1 vertical, and a large area should be provided so that the accumulation from a single discharge will not completely blind the rack and form a dam.

A velocity of about 1 ft. per sec. for a period of from 1 to 2 min. is the best for removing the grit. Heavy material settled in this way should not average more than 5% organic matter and, ordinarily, will not be offensive.

Grit-chambers, 10 or 12 ft. wide arranged in parallel channels, will be convenient and, if desired, may be operated automatically by floats designed to cut in or out a sufficient number of channels to care for the flow at approximately the desired velocity. The grit may be excavated by a clam-shell bucket, removed in trucks or cars, and used for filling.

The finer screenings may be handled in various ways. When at or near a sewage disposal plant, mechanical screens may be used. At the lower end of a grit-chamber, 10 or 12 ft. wide, carrying about 40 000 000 gal. per day, a 12-ft. R.-W. screen, or a 12-ft. Dorrco screen 10 ft. long, may be used if properly housed and provided with power.

Another method would be to construct the grit-chamber or basin with the upper part of the side next to the stream of open permeable material, so that water may pass through it leaving the screenings deposited on its surface. Maintaining a proper velocity through the chamber and keeping the porous bank from clogging would be the chief difficulties with this design.

Another suggestion which has considerable promise, is a grit-chamber preceded by coarse racks and provided at intervals of about 25 ft. with several sets of inclined scum-boards continued downward with inclined racks, progressively finer down stream, each of which is provided with raking platforms above and short submerged platforms projecting up stream from their lower ends to retain the screenings. These racks will not reach the bottom of the chamber, but will stop about 4 ft. above it. The down-stream end of the chamber will consist of an overflow weir which will maintain the water in the channel at the desired elevation. A drain valve for re-watering will also be provided.

All such devices will require periodic attention and cleaning and cannot be operated satisfactorily, except on a methodical schedule directed by a responsible man.

As previously mentioned, structures for treating storm-water may be made up conveniently of units about 10 or 12 ft. wide by a maximum of 10 ft. deep and from 60 ft. to 120 ft. long, designed for a velocity of 1 ft. per sec. The number of such units will depend on the quantity of storm-water antici-

pated, assuming the capacity of each channel to be 60 cu. ft. per sec. Either there must be a sufficient number of such units to carry the estimated maximum flow, or a smaller number may be constructed and a by-pass provided, as economy may dictate.

The simplest way of accommodating an extreme flow would be to construct the walls of the channels with considerable free-board, in order that an increased head on the outlet weir would accommodate the increased discharge.

As an example of about what would be required, let us assume a water-shed of 1 000 acres, 1 mile wide, and nearly 2 miles long, with the longest sewer 12 000 ft. in length from source to outfall, and with grades such that, when running full, the velocity will average 5 ft. per sec. It will require, therefore, 40 min. for water to travel down the entire system, and if a period of 5 min. is allowed for the water to reach the sewer, a shower of 45-min. duration will be the shortest in which the entire water-shed will contribute and precipitation from the remotest corner of the territory reach the outfall at the same time as from every other part. If from an examination of the rainfall records of the locality, one selects the 45-min. shower of such intensity that it occurs every year or two, it may be used as a basis for the computation of the run-off to be provided for at the outfall.

In Rochester, N. Y., this 45-min. shower has a rate of 1.22 in. per hour. In the residential section about 25% of the precipitation from these violent showers reaches the sewers during the period. A discharge of $1\,000 \times 1.22 \times 0.25 = 305$ cu. ft. per sec., therefore, can be computed, which will require five of the grit-chamber units mentioned. Such a plant will take the discharge of a 9-ft. sewer at a grade of 1 in 1 000, or a 7-ft. sewer at a grade of 1 in 280.

This may be roughly stated as three of the previously mentioned detritus chamber units per square mile of tributary territory, subject, however, to wide variation, depending on the rainfall, slope, and character of the territory. A similar approximation would place the cost of construction of such a detritus plant at from $10 000 to $12 000 per square mile of territory.

It is appreciated that little has been done in storm-water treatment and that the health authorities have been interested chiefly in the protection of streams from other pollution, but the time may be anticipated when the concentrated storm-water discharge of cities will demand attention.

POLICIES OF THE ENGINEERING DIVISION OF THE PENNSYLVANIA DEPARTMENT OF HEALTH AS TO PUBLIC SEWERAGE

By W. L. Stevenson,* M. Am. Soc. C. E.

In 1905, the Legislature of Pennsylvania enacted the "Purity of Waters Act" for the protection of the public health by controlling public water supplies and by prohibiting the discharge of sewage into the waters of the State.

The Act, however, provides that, in the case of municipally owned sewers, the Commissioner of Health, with the unanimous agreement of the Governor and the Attorney General, may permit the discharge of sewage subject to such conditions as he deems will subserve the general interests of the public health.

The evident intention of this prohibition and provision for discharge under certain conditions is to provide for varying degrees of sewage treatment, so as to maintain the streams in a reasonably clean condition and to make it practically and economically possible to use certain waters of the State as sources of public water supply and for other purposes requiring a hygienic standard.

Streams are the natural drainage channels for rain water flowing over the surface of the land and conveyed to them by storm-water conduits from the towns on their water-sheds.

It follows, therefore, even if all the sewage was excluded or completely purified, that no surface water from a populated water-shed would be fit for use as a public water supply without some form of purification to eliminate the natural contamination of the surface stream.

It is possible to produce a clean, colorless, and bacteriologically safe water supply from a grossly polluted and contaminated source. It is also possible to purify sewage to such an extent that it will be freed from all its polluting and contaminating constituents; but both procedures are exceedingly costly and often unreliable. Therefore, a wise and just administration of the "Purity of Waters Act" should be based on an economic consideration of the uses and conditions of the various waters of the State so as to secure the greatest protection to the public health by the least expenditure of public and private funds for the construction and operation of water purification and sewage treatment works.

The Engineering Division of the Pennsylvania Department of Health is charged, among other things, with the examination of plans of sewerage and sewage treatment works, submitted with applications for issuance of permits; also, with making field investigations and recommending to the Commissioner of Health the conditions under which permits may be issued.

Certain fundamental policies have been established to obtain as nearly as possible uniform practice in this work, but it must be borne in mind that the wide range of uses and conditions of the waters of the State makes it

* Asst. Chf. Engr., Pennsylvania Dept. of Health, Harrisburg, Pa.

utterly impracticable to follow detailed policies that will be State-wide in application.

In this discussion, the word, "stream", is considered as including all lakes, ponds, or other waters of the State, and where policies are given for streams used as sources of public water supplies, they apply equally to streams used for other purposes requiring a hygienic standard, such as bathing and ice harvesting.

Classification of Streams.—The problem of administering that part of the "Purity of Waters Act" relative to sewerage has three phases: (1) prevention or abatement of nuisance; (2) protection of sources of public water supply; and (3) maintenance of clean streams.

Even though they are not used as sources of public water supply, streams as a matter of decency should be maintained in a reasonably clean condition, that is, free from sludge deposits on the bed or banks, ebullition of offensive gases, undue turbidity, discoloration, floating solids, or any other nuisance to sight or smell of sewage origin.

In addition to being reasonably clean, streams used as sources of public water supply should provide a raw water sufficiently low in organic and pathogenic bacterial content that it can be purified safely and economically for domestic purposes.

Small streams flowing through highly developed suburban territories or land devoted to park purposes for the pleasure and recreation of the public, demand a high degree of protection and should be so clean that they show no appreciable evidence of sewage.

Degree of Sewage Treatment Required.—The ground-water drained or pumped from coal mines contains considerable sulphuric acid which acts as a germicide on sewage discharged into streams receiving such mine drainage, thus minimizing the danger of creation of nuisance or menace to the public health; also, these streams frequently carry large quantities of fine coal which mask any visible evidence of sewage matters. Therefore, at points reasonably remote from water-works intakes, sewage generally may be discharged untreated into these streams, but preferably from the outlets of the several drainage areas and always into the main current of the stream, in order to prevent local nuisance at the immediate point of discharge and to distribute the sewage more effectively in the stream and thus take full advantage of dilution by the water of the stream and the germicidal action of the acidity.

If the rate of flow and velocity of streams not used as sources of public water supplies are insufficient to assimilate crude sewage inoffensively, then such a degree of treatment should be required as will lighten the load of organic matter on the stream so that the desired conditions of cleanliness will be maintained, even during times of drought.

The assimilating power of the stream should be distributed equitably among the various municipalities along its course, so that one town will not be required to treat its sewage to a high degree because a neighboring community up stream has overtaxed the stream with insufficiently treated sewage.

In the case of streams used as sources of public water supplies, sewage treatment should be required to a sufficient degree to produce an effluent which, after being carried by the stream to the water-works intake below, will not prejudice the safe and economical purification of the water for domestic purposes.

Ample diluting water and sufficient distance between the water-works intake and the place of sewage discharge may reduce the required treatment of sewage to a negligible degree.

Cleaning Streams.—The cleaning of sewage-polluted streams not used as sources of public water supplies or the maintaining of such streams in a clean condition should begin at the upper end and progress down stream.

In general, action taken to protect streams used as sources of public water supplies, subject to local conditions, should begin at the first source of sewage contamination above the water-works intake and progress up stream.

Sewer System.—Every municipality should prepare and submit to the State Department of Health for approval, a comprehensive plan of sewerage before undertaking the design of new sewers or the extension of existing sewers, as may be needed from time to time.

In sewering new drainage areas, comparative estimates of cost should be made of:

1.—Collecting sewage and rain water in separate conduits; and
2.—The use of the combined system with interception of all dry-weather flow of sewage and such a percentage of storm water contaminated with sewage as will afford the required degree of protection to the receiving body of water.

In extending existing combined sewers in municipalities having well improved highways, the relative economy of continuing the combined sewers, or of replacing them with separate sewers, should receive careful consideration in connection with the relative protection afforded to the waters of the State.

Contiguous or adjacent municipalities should be urged to give careful study to the possible advantage of entering into agreements for the joint construction and operation of intercepting sewers and sewage treatment works.

Sewage Treatment Works.—In cases where sewage treatment is not required at present, general outline plans of the project should be submitted to the State Department of Health for approval. They need only be prepared in sufficient detail to demonstrate the feasibility of constructing the intercepting sewers and sewage treatment works and to show that the site of the proposed work is properly located, ample in area, and of suitable topography for the erection of treatment works sufficient for the needs.

The advance in the knowledge of sewage treatment in past years indicates the possibility of even greater improvements in the future, and, therefore, it is inadvisable to prepare detail plans until it becomes necessary to construct the works.

If the approved site is likely to be acquired for private use, the municipality should forthwith acquire it, so as to be prepared to treat the sewage when necessary.

In cases where the use and condition of the stream is such that sewage treatment is required, the plans should show in detail that part of the works required for the needs of the present and reasonable future and, in general, outline the extensions required for the increased rate of flow and higher degree of treatment that may be needed in the more distant future.

The operation of oxidizing processes of sewage treatment works, the only purpose of which is to prevent the creation of a nuisance in a stream not used as a source of public water supply, may, on request and with the specific approval of the State Department of Health, be suspended during the colder part of the year, when the greater quantity of dissolved ogygen and lessened biological activity in the stream will permit the discharge of unoxidized sewage.

STREAM POLLUTION AND ITS CONTROL

By Earle B. Phelps,* Affiliate, Am. Soc. C. E.

A complete statement of the problem of the control of stream pollution, aside from its purely legislative and administrative aspects, involves three essential terms capable of expression in common units. These are: The capacity of the stream; existing or contemplated pollution load; and, means of reducing the pollution load.

Every stream has a certain maximum capacity for the biological disposal of common organic wastes. According as local circumstances permit a greater or less depletion of this natural reserve of capacity, with consequent temporary reduction in stream quality, any stream may be said to have an effective working capacity for waste disposal which is a function of the fixed maximum capacity and of the permissible quality depletion. The latter varies according to circumstances and usage, but the lower the standard of minimum acceptable quality the greater the working capacity of the stream for waste disposal.

This working capacity is not a mere capacity for dilution. It comprises all those bio-chemical reactions which make for the self-purification at the stream. A pollution load of stated amount brings about, within a certain distance (the critical point, measured down stream in hours), a definite reduction in stream quality, after which the operation of self-purification becomes predominant and stream quality rises again toward normal. A greater load produces a proportionately greater reduction in quality at the critical point, and subsequent recovery is proportionately delayed.

The maximum load previously referred to, may be defined as that load which, at the critical point, produces conditions inimical to those agencies which bring about self-purification, so that improvement of the stream beyond that point is either greatly delayed or altogether lacking.

Although the available data in this field of investigation are too meager to justify any definite generalization for all streams, yet the methods of investigation have been developed sufficiently at the present time to permit the determination of the fundamental stream constants, the critical point, the maximum capacity, and the rate of self-purification in the case of any stream of known physical characteristics and pollution load. By the aid of these constants, the effect of added or diminished pollution load can be determined and, conversely, for any fixed lower limit of quality, the working capacity of the stream becomes known. This information is the first prerequisite in any comprehensive program for the control of stream pollution.

A more detailed account of the various subdivisions of this phase of the problem is not possible in this discussion, further than to indicate that it is not simple, but is essentially dependent on sedimentation, additional pollution or dilution in the lower stretches, and re-aeration; and that the latter, the most significant factor of all, is a function of depth, velocity, turbulence, and other physical conditions.

* San. Engr., Ridgewood, N. J.

It must further be pointed out that all references to stream quality must be in terms of a unit which may also be used in measuring the pollution load and the effect of remedial measures, the so-called oxygen unit, to which reference will be made later.

The second term in the stream-pollution formula is the pollution load. This phase also is complicated in practice and may be dealt with only in general terms in the present summary. Obviously, the oxidation of organic matter in the stream is a time function so that a first approximation to a statement of pollution load must be in terms of total oxidizability and rate of oxidation at each degree of completion. Given this complete oxidation curve, at any stated load, the effect on a stream of known capacity could be determined. Fortunately, the form of this curve has been established so that two determinations on the oxidizability of a waste, taken, say, at 24 and at 48 hours, furnish the necessary and sufficient data. This treatment assumes, however, that all the pollution travels uniformly with the stream up to the point of complete disposal. If a part of the waste is capable of settling and the stream characteristics permit of sedimentation, the oxidation characteristics of the settleable and the non-settleable parts must be dealt with separately with appropriate time factors.

The methods by which the pollution load is measured in the laboratory have served to indicate the only satisfactory unit of measurement for stream quality. The earlier work in this field attempted to deal with pollution in terms of nitrogen and to establish some empirical relation between the content of unoxidized nitrogen in the stream and that elusive factor, stream quality, for which there was no adequate direct measure. These attempts were theoretically unsound and led only to greater difficulties and to such fallacies as the establishment of a constant dilution ratio for sewage in a stream, which was supposed to mark the boundary between safe and unsafe practice. The newer chemistry deals wholly with oxygen units, as these units measure pollution load as well as stream quality and are interchangeable between the two when once the fundamental formulas have been derived. The characteristics of the most important polluting agent, domestic sewage, have been quite satisfactorily determined and are referable to the population base, thus eliminating the former difficulty of determining the strength and total volume of the sewage, neither of which *per se* has any but incidental relation to the question of pollution load. Much information has also been accumulated concerning the characteristics of certain of the more important industrial wastes, such as the waste from tanneries, soap works, and others. Here, too, the attempt has been made to refer the pollution load to the reference base, manufactured product. It is obvious that there must be some fairly constant amount of pollution resulting from the cleansing and tanning of a single hide by a standard procedure, regardless of the quantity of water in which the waste is carried to the stream.

With the determination of the stream constants and of the present and prospective pollution loads, the condition of the stream resulting from any assumed increase or decrease in the load may be stated with reasonable approximation. If this condition requires improvement, the degree of

improvement decided on is also capable of expression in terms of the pollution load. The problem then becomes one of treatment of the polluting wastes to the required degree. Except in certain fields, such as the treatment of domestic sewage, this leads to experimental studies of remedial measures which are essentially chemical or biological in nature, rather than engineering. Domestic sewage has been sufficiently investigated so that the engineer now has at his disposal the necessary bio-chemical data to enable him to design works for any specific degree of reduction of the pollution load. A proper appreciation of the basic principles of stream pollution, however, will enable him to design scientifically for the utilization as well as for the protection of the stream, a matter which has been too often overlooked. A considerable field of activity in the remedial treatment of industrial wastes is still open to investigation. Many of the wastes do not lend themselves to the line of procedure suggested by the speaker. The effects of some wastes, such as saw-mill refuse, are purely physical, while the effects of others are purely chemical; the acid residues from certain iron works are an example of the latter. In the majority of cases, however, the effect is bio-chemical, and the results of experimental studies are best stated in terms of oxygen demand pollution units which can be compared directly with the stream capacity similarly stated.

Thus, a scientific basis is laid for the study of this problem of stream conservation which, properly understood, means the maximum utilization of stream resources. In addition to the three scientific aspects of the problem, there are the legislative and administrative aspects without mention of which this discussion would be incomplete. The matter has been placed last, however, because it should rest wholly on a correct understanding of the fundamentals. Much harm has been done to real progress by inverting this natural order and through misdirected legislation, seeking an impossible perfection which has only invited disrespect and lack of enforcement. The successful stream-pollution legislation of the future will give wide discretionary power to capable administrative bodies whose duty it will be to determine stream resources and capacities and to distribute these so that a maximum utilization will be made possible. The interstate character of most of the great streams of the United States, and the magnitude of the problem in both its investigative and its administrative phases suggest Federal control as a probable final outcome. This is emphasized more particularly by the present failure of most of the States to deal with the problem on any comprehensive basis.

The matter of stream pollution and its control is now essentially one for the health authorities. Historically, it has had conspicuous public health aspects, but time has been lost and attention misdirected by too close adherence to this traditional treatment. The problem of stream pollution is clearly one of conservation of a natural resource with, at times, a public health aspect which is always paramount when present, and, at other times, an overshadowing commercial and industrial aspect. In short, it is a problem in the maximum utilization of an economic resource and its future development should be placed in the hands of an authority having the widest possible scope and the broadest jurisdiction.

DEPOSITION OF SLUDGES RESULTING FROM SEWAGE DISPOSAL PLANTS

By T. Chalkley Hatton,* M. Am. Soc. C. E.

The problem of sewage disposal will be presented herein from a different angle than that usually discussed in papers on this subject, and the speaker would like to emphasize a certain viewpoint.

Sewage disposal embraces two distinct problems, the partial purification of the liquor and the final disposition of the resultant sludge. Up to the present time the great bulk of scientific labor has been devoted to solving the first problem, the solution of the latter having been left largely to chance.

The speaker believes that the reason for this is principally economic; that the nuisance to our neighbor using a stream polluted by our sewage demands its partial purification, whereas the disposition of the sludge is more likely to be a nuisance from which we alone may suffer.

Science has discovered several processes of purifying the liquor to any standard which may be required to prevent a nuisance, but the speaker is not so sure that it has been as successful in disposing of the sludge, and he is firmly convinced after many years of intensive study of this phase that sanitary engineers should give it far more consideration than they have.

Engineers cannot expect to make sewage disposal popular with the public if about the disposal plants are spread foul smelling, dirty looking, putrefactive piles of material that breeds flies and vermin which the surrounding population believe infect their properties.

A casual inspection of the sewage disposal plants of England when the sludge is being disposed of on property adjacent to the works convinces the engineer that the work is being only half done, and from personal inspection in 1907, and again in the early part of 1921, the speaker can state positively that, as far as he was able to judge, no improvements worthy of note had been made in the 14 years, and that the nuisance had so multiplied as to threaten the welfare and health of large numbers of people.

Take the experience on this Continent and consider the nuisance being maintained from sludge disposal at Toronto, Ont., Canada, and at Baltimore, Md., two of the largest cities on the Continent which are operating modern sewage disposal plants.

In both these cities, suits have been brought and damages recovered for nuisances arising from sludge disposal. Mr. Marks, of the Pennsylvania State Board of Health, has stated to the speaker that the present methods of disposing of sludge in the sewage disposal plants in Pennsylvania were becoming an unmitigated nuisance and some other means would have to be devised.

There is not a sewage sludge produced from any sewage disposal process in which lime is not used, but that has some value as a fertilizer. Such sludge will be sought by the agriculturist if it can be delivered to him in a condition in which he can handle it conveniently, and the speaker believes that is the

* Chf. Engr., Sewerage Comm., Milwaukee, Wis.

final solution of the problem. It will cost far more in some, in fact, in many, instances to procure this condition than the returns from the sale of the sludge; in fact, there may be instances when no monetary returns whatever will be secured.

Whether it does or does not return a monetary value directly, it does get rid of the filth of the human body in the only logical way by returning it to the soil from whence it came, and indirectly will pay just as the purification of water supplies has paid.

Engineers have had the direct economic viewpoint too much in mind to study this sludge problem properly, and as municipal engineers charged with improving the sanitation and welfare of the communities they must look on it with a broader vision or sewage disposal as a science will never attain the place it deserves.

The viewpoint of the German engineer has been different from that of the English and the American engineer. He has not been as anxious to produce a stable effluent as he has to get rid of the sludge in a way which may add to the wealth of his community, and one who goes about the German sewage disposal plants to-day will be struck with the entire absence of piles of sewage sludges. If one wants to see them, he must travel about the neighboring farms where they will be found placed in compost beds to be used to fertilize the soil as the season demands.

The speaker desires to give just one illustration of what can be done by a little useful and intelligent propaganda among the farming community adjacent to a sewage disposal plant.

The city authorities of Rochester have built and operated one of the largest Imhoff tank systems of sewage disposal in the United States. It was designed to dry the sludge produced on beds and dump it into a beautiful valley adjacent to one of the fine parks belonging to the city. The engineer in charge of the works soon realized that this would finally result in a nuisance, and he went among the fruit growers near-by and induced them to try some of this partly dried sludge on the ground about the trees.

The next season these growers hauled away all the sludge they could and paid a small sum therefor. The demand became so great the following season that the price was increased about 50%, but this increase had no effect and, to-day, the sludge is being disposed of at about the same price which it costs to de-water and deliver it to the customer. It is believed that in another season or two the authorities will be able to dispose of all the sludge the plant will produce. What this engineer has done, other engineers can do, if they go about it in the right manner, but they must first get the vision that the sludge must be disposed of finally by putting it back on the ground regardless of the cost.

Sludges have been successfully de-watered in several places in America and in Germany. At Providence, R. I., and at Worcester, Mass., filter presses have been used for many years, while in Germany centrifuges have been used with equal success. In Baltimore, during the past five years, much of the sludge has been de-watered at 12 and 15% and sold as a fertilizer, and about 25 tons per day of dry material is thus being produced.

Whether or not the Baltimore experiment is self-supporting, the speaker cannot state, as he knows nothing of the cost of the overheads. The original contractor who undertook this work four or five years ago is still on the job, although his original contract was for two years only. How he continues with the present lack of demand for fertilizer is more than the speaker can tell, but he is continuing nevertheless. The contract thus far has been profitable to the city.

In Milwaukee, this sludge-disposal problem has been studied for five years, and although it has not been solved satisfactorily, the point has been reached where the moisture content has been reduced by sludge presses and dryers to 10%, and if the demand for fertilizer is restored to pre-war conditions, it will be possible to dispose of the sludge for at least what it costs to produce it and probably a profit will be enjoyed.

THE DILUTION FACTOR

By Langdon Pearse,* M. Am. Soc. C. E.

Discussion of stream pollution in the early days appears to have centered mainly on the standpoint of nuisance. As concentration of population has increased, together with the load on the stream (or other body of water), other problems have entered, such as the effect of the sewage and sludge on fish life, shellfish, and bathing. In more recent years, in many localities, consideration has been demanded for the degree of loading which can be handled by a water purification plant. From this gradual development, two widely distinct dilution factors may be said to have arisen, one relating to prevention of nuisance, the other due to prevention of undue load on the water purification plant. On the first of these factors, considerable data are available; on the second, comparatively little is known as yet. The purpose of this brief discussion is not so much to summarize existing data, as to point out the need for well considered investigations over considerable periods of time on stream pollution problems, and to cover quantitatively the subject of loads on water purification plants.

In the problem of stream pollution, the dilution factor of nuisance is of prime importance and has provoked discussion covering the past 35 years. Many authorities have endeavored to state this factor on a basis of cubic feet per second per 1 000 population. These bases have been largely varied by the type of city studied, and the character of the stream, as shown by results in Massachusetts and elsewhere. In general, a range of from 4 to 7 cu. ft. per sec. per 1 000 population has been indicated, with a lower limit of 2 and an upper limit of 10 cu. ft., according to the authority.

In England, high dilutions have been recommended by the Royal Commission, as noted by Mr. A. J. Martin, upward of 27.8 cu. ft. per sec. per 1 000 population having been mentioned.

In the problem of the Sanitary District of Chicago, an expression was early sought for a somewhat different angle of attack, namely, for the amount of oxygen required. For this determination, the bio-chemical oxygen demand test has seemed to be the most favorable. Continued tests on a large sewer serving 300 000 people, with no marked industrial wastes, have given an equivalent of 0.22 lb. of oxygen per capita for complete oxidation. This requirement is based on an incubation period of 10 days, in sealed bottles, and takes no account of re-aeration factors.

Inasmuch as the oxygen content of water varies with the temperature, for translation into more familiar equivalents, Table 1, based on the 0.22 lb. per capita, may be helpful. The figures given therein are indicative of what would be needed if no re-aeration was to occur. The re-aeration factor should reduce the flows required per 1 000 population. Of the oxygen requirement, roughly, about from 20 to 30% seems to be necessary in the first 24 hours.

* San. Engr., The San. Dist. of Chicago, Chicago, Ill.

TABLE 1.

Dissolved oxygen, in parts per million.	Temperature corresponding to dissolved oxygen saturation, in degrees Fahrenheit.	Flow required in cubic feet per second per 1 000 population.
6	108	6.80
8	81	5.09
10	60	4.07
12	46	3.40
14	35	2.92

Present observations on the Main Channel at Chicago appear to indicate that a higher dilution than the minimum of 3.33 cu. ft. per sec. per 1 000 population is required to dilute the raw sewage of domestic origin, in the summer; between 4 and 5 cu. ft. per sec. now seems to be nearer the requirement. With an industrial load at times more than 50% of the human load, the need of much higher dilution for both domestic and industrial sewage combined is apparent. The exact figure will depend on re-aeration factors and seasonal conditions, such as temperature and the extent of the ice sheet, as well as the standard of dissolved oxygen to be maintained at critical points.

Data on re-aeration are needed. The extent will depend on the swiftness and turbulence of the stream. In traveling from Marseilles to Chillicothe, Ill., a distance of 65 miles, the Illinois River absorbed about 205 000 lb. of oxygen from the atmosphere, on one test, approximately 3.8 parts per million.

From the standpoint of sewage dilution, the problem is reduced to the determination of the amount of pollution to be handled and the amount of oxygen available plus re-aeration. To make a balance, additional dilution, or supplementary treatment, may be required. The exact solution will hinge also on the rate of oxidation and the amount of residual oxygen desired at critical points.

The amount of residual oxygen to be preserved will depend on the conditions to be met. Where nuisance alone is to be avoided, there seems to be little doubt but that some residual oxygen must be present. This may not prove to be sufficient to prevent odors from decomposing sludge banks.

From the standpoint of fish life, considerable oxygen is required. Although fish may live in low oxygen content for a short time, they cannot survive long. Fish specialists suggest not only the study of the oxygen content, but also the carbon dioxide and the hydrogen-iron concentration.

A number of years ago, Dr. Arthur Lederer and the writer made an extended investigation of the fish question for the Sanitary District of Chicago, with the following conclusions:

1.—Fish life is affected by material in suspension and solution, and the variations thereof.

2.—Material in suspension may cause disease by fungus growths or death by mechanical stoppage of the gills or suffocation thereby. The character, size, and quantity of the material must be considered. A careless and continuous handling of fish may induce fungus growth through the abrasion of the slimy, protective coating of the body, thus allowing foreign bodies to adhere.

3.—Material in solution includes mineral and organic matter and gases. The investigation covered only dissolved oxygen, which, of the gases in solution, was the most important in this case.

4.—For continuous fish life, a content of dissolved oxygen of at least 2 to 3 parts per million is required by practically all the fish used in the investigation.

5.—The fish studied may live for very short periods in a content of dissolved oxygen of between 1 and 2 parts per million. This provides time for the fish to escape to better conditions, if any are available.

6.—English observations, as well as German experiments, indicate that, in general, 25 parts per million of dissolved oxygen are about the minimum for fish life and that for continuous thriving fish life more is desirable. In the light of the experiments in America, it appears that many species will live in 25 parts per million, but that more is desirable.

7.—Sudden changes in the character of the environment are undesirable and may cause the death of the weaker specimens.

8.—Of the fish experimented on, their vitality or their relative ability to withstand low contents of dissolved oxygen, is roughly in the order designated as follows, the strongest being listed first, the weakest last: German carp (from Illinois River); catfish and bullhead (from Illinois River); black bass (from Illinois River); yellow perch (from Lake Michigan); and sunfish (from Lake Michigan). The pickerel and golden shiner apparently are to be classed with the sunfish. Further data, however, are desired, as the tests on these two species are not as extended as on the others named.

An extended joint investigation by the U. S. Public Health Service and Sanitary District of Chicago has been undertaken which will cover in detail the self-purification of the sewage of the District from Lake Michigan to the Mississippi. Many of the points suggested herein will then be elucidated. The effect of re-aeration, temperature, ice sheet, time or length of travel, and sludge travel, are to be studied, and existing data will be summarized. With the work already done by the Public Health Service on the Potomac River and the Ohio River, this third investigation should provide useful data for all students of stream pollution problems.

The dilution required to prevent an undue load on water purification plants appears to have been first cast in definite form in the work of the International Joint Commission. The standard suggested was that the average load on such a plant should be such that the raw water would not contain as a yearly average more than 500 *B. coli* per 100 cu. cm., or, as translated by Professor Phelps, a dilution of 4 cu. ft. per sec. per capita or greater should not produce an undue load.

In a paper entitled "The Loading of Filter Plants", H. W. Streeter, Assoc. M. Am. Soc. C. E., has discussed the problem in some detail from the standpoint of the efficiency of the filter plant, corroborating in general the report of the International Joint Commission. However, he suggests the need of more data and a definite adoption of a standard for filtered water.

Many filter plants delivering a reasonably safe potable water, judged by the typhoid fever death rate, handling raw waters more polluted than those mentioned. How safe they will be, experience alone will tell. The need at present is for careful standardized tests of such plants in order to determine the data along common lines. The U. S. Public Health Service has made an extended survey of the Ohio River Basin, and more studies might be made

available from scattered plants, by the more general adoptions of standard methods of analysis and report.

Such data will be helpful in solving the problems ahead, not only on the Great Lakes, but on many of the large rivers of the United States. Further, such data will be helpful in crystallizing the policy of various State board of health authorities who have jurisdiction over different parts of the same stream, as in the case of the Missouri River from Kansas City to St. Louis, Mo.

There is, at the present time, need of a sane, well-considered viewpoint, looking ahead, not only from the standpoint of nuisance, but from the standpoint of fish life, and in many cases of drinking water. Various organizations of sportsmen, nature lovers, conservationists, and others are urging the restoration of streams to their former condition of virgin purity. How far it is necessary or possible to go in each individual case is a question for the engineer to solve. For the solution, every available experience helps.

The writer desires to acknowledge the courtesy of the Trustees of the Sanitary District of Chicago and of Albert W. Dilling, Assoc. M. Am. Soc. C. E., Chief Engineer, for the use of certain data contained herein.

PREVENTION OF MISUSE OF SEWERS

By W. H. Dittoe,* M. Am. Soc. C. E.

The purpose of this discussion is to call attention to the abuse of sewerage and sewage disposal systems resulting from failure of municipal officials to control properly the establishment and use of connections to sewers. Sanitary engineers generally have deplored this condition of affairs and, as a class, are in agreement that better control should be provided. However, they have been prone to leave entirely to municipal officials the solution of this problem and with few exceptions have failed to recognize that it is essentially their duty to take the lead in establishing proper control. This discussion will attempt to show that sanitary engineers must not only recognize the importance of preventing abuse of sewerage and sewage disposal systems, but must undertake the problem of prevention if the expected efficiency of such improvements is to be realized. The speaker will not recite instances to demonstrate the evil effects of misuse of sewerage systems, with which all engineers are familiar, but will confine this discussion to general statements with the hope of arousing an interest on the part of engineers in attacking a solution of this problem.

One of the most important factors reducing the efficiency and value of systems of sewerage and sewage disposal is the misuse of sewers. Sufficient emphasis has not been placed on this subject, and rarely is it found that a municipality enforces a strict policy regarding the use of sewers. Considerable effort is expended by engineers in designing sewerage systems and sewage disposal works and, as a basis for such design, the volume and character of the sewage flow must be known or estimated. Therefore, if these factors are disturbed appreciably, the improvements will not be used under the conditions for which they were designed. The result will be a shorter life of the system as a whole, impairment of its efficiency, and generally unsatisfactory results. The misuse of sewers is also an important fault affecting the successful operation of sewage disposal works, and, therefore, the problem of prevention of stream pollution. It is useless to design sewerage improvements on an assumption that certain maximum rates of flow will occur and that the sewage will be of a certain character, unless the construction of such works is followed by the enforcement of a definite policy which will insure against exceeding such rates or changing such character.

Sewers are designed for definite purposes and when used for other purposes may be said to be misused. Storm drains are misused if they receive sewage, industrial wastes, or other waste of objectionable character. Combined sewers are properly used for the removal of practically all classes of liquid wastes, but are misused if they receive industrial wastes affecting the sewerage system or process of sewage treatment. Sanitary sewers, as the name implies, are for sanitary purposes only, and are misused if they receive drainage from the surface and roofs, subsoil drainage such as may be admitted by building foundation drains and through open or leaky joints, and industrial wastes of a character to affect the sewerage system or treatment process.

* Chf. Engr., Ohio State Dept. of Health, Columbus, Ohio.

The effect of the misuse of sewers is frequently quite serious. Sewage discharged into storm sewers causes nuisances at outlets and offensive odors through street inlets. If such practice is permitted, the benefits to be expected from a separate sewerage system are not realized. The admission of surface and subsoil drainage to sanitary sewers overtaxes the sewerage system, resulting in cellar flooding and damage to sewers, and overburdens the pumping equipment and sewage treatment works, necessitating by-passing of the flow, impairing the efficiency of the plant, and frequently causing rapid deterioration. Industrial wastes often cause clogging or may actually destroy the sewers if the wastes have solvent properties. Many industrial wastes also interfere seriously with the efficiency of sewage treatment plants. Of the more troublesome industrial wastes, may be mentioned: Wastes from tanneries and glue factories containing hair and lime; wastes from textile industries containing cloth, fibrous material, and objectionable compounds in solution; wastes from canning factories containing vegetable particles; wastes from stockyards containing manure; wastes from packing plants containing animal offal; gasoline wastes from garages; acid wastes from metal industries; wastes from milk industries; and gas-house wastes. Such wastes should be treated properly prior to their discharge into the public sewers, or they should be excluded entirely.

It seems apparent that the evils resulting from the misuse of sewers are of sufficient importance to warrant an effort to prevent it. It has been accepted by many engineers that the misuse particularly of sanitary sewers to carry storm water, is inevitable and cannot be prevented, and this conclusion has produced a strong argument for the selection of the combined system. It is true that the combined system can rarely be misused and that from this standpoint it is preferable; however, it does not appear sound to conclude that it is impracticable or impossible to secure the proper use of separate systems. In fact, separate systems now in existence will continue in use and new systems will be built; therefore, engineers and city officials cannot avoid the responsibility for securing their proper use. The industrial waste menace is present and must be controlled regardless of the sewer system used.

It is obvious that the proper use of sewers cannot be secured without strict enforcement of ordinances and regulations by the proper municipal officials. The sewer contractor and the property owner cannot be expected to realize the importance of using the sewers properly and for the purposes for which they were designed to function, and, therefore, they must be controlled in order that the public may not suffer from their mistakes. Ordinarily, municipal officials themselves do not appreciate the necessity of protecting sewers and sewage treatment plants from abuse, and, therefore, are not in a position to initiate suitable regulations. It seems apparent that it becomes the duty of sanitary engineers to dictate such regulations and to see that they are adopted. This function of the engineer is as important as the design and supervision of construction of the improvement, and if it is not performed it may truly be said that the work of the engineer has not been complete. Ordinarily, the engineer who has designed and supervised the construction of a sewerage system and a sewage treatment plant furnishes definite instruc-

tions in regard to the operation and maintenance of the system, and he should likewise furnish a definite program for preventing misuse which may defeat the purpose of the improvement.

Many municipalities have satisfactory ordinances and regulations, but fail to enforce them. Such ordinances usually require permits for connections to the sewers and provide for inspection of the connection by a representative of the municipality after the contractor has completed the construction work and before the trench is filled. Theoretically, this control should be sufficient, but too frequently the results are far from satisfactory. In many instances, the construction work is faulty, joints are made imperfectly, admitting ground-water to the sewer, the inspection is neglected or performed carelessly, improper wastes are admitted, and no proper record of the connection is maintained. When this system of control is started improperly, it is difficult to correct it and make it efficient, and usually the conditions become worse rather than better, until the sewer system is generally abused.

It seems necessary that municipalities provide a more immediate and direct control of the use of sewers, if sewerage systems are to be managed and maintained as they should be. The most logical and effective method of accomplishing this is the construction by the municipality of all connections to the public sewers from the building to the street sewer and the continuation of municipal control over such connections after they are constructed. The sewer department would organize its construction gangs for this work or would enter into annual contracts with responsible contractors, and the property owner would pay to the city the cost of construction, inspection, and recording.

When local treatment of industrial wastes is necessary to protect the sewerage system or sewage disposal works, such treatment would be provided by the industry and the effluent received into the sewer system under proper control. The connection could be equipped with an inspection hole to permit subsequent examination by the sewer department of wastes discharged through it, and the discharge of prohibited wastes could thus be detected. It is believed that this method would insure better construction of the connection at lower cost, would largely prevent the misuse of sewers, and would assist in securing efficient operation of sewage treatment processes. Incidentally, it would probably arouse a more lively interest on the part of the city officials in the management and maintenance of the sewerage systems and would likewise remind the public that the system is an important feature of the community development and must be controlled in a business-like manner if its value is to be realized.

DISCUSSION

HARRISON P. EDDY,* M. AM. SOC. C. E.—One item not mentioned by Mr. Hammond is important, namely, the effect of temperature on the period which should be provided for sludge storage in the digestion tank. Presumably, the eight months mentioned refers to the climatic conditions of Brooklyn, N. Y. In the north, digestion is confined in large measure to the warmer months of the summer, and storage of the sludge is required over a considerable part of the year. The same treatment in a warm climate where digestion can proceed throughout the year at a nearly uniform rate, may require a very different period of sludge storage, and, therefore, it would seem important to consider temperature conditions as well as the quantity of solids in the sewage.

The point presented by Mr. Stevenson in connection with the seasonal operation of sewage treatment plants is also important. Although, from some points of view, it is desirable to deal with this subject in an idealistic manner, it is probably not wise to disregard economic conditions. The following illustration may be cited to show that it is practical to operate a plant according to climatic and physical conditions. A certain plant on a relatively small stream was equipped with various means of treating industrial wastes. These wastes are first screened and then passed through sedimentation tanks, after which they are treated by chemical precipitation; and, finally, the treated liquor is passed through sand filters. On a branch of the stream there is a reservoir with a capacity of about 300 000 000 or 400 000 000 gal. For a number of years, this plant has been operated according to climatic conditions. In winter, screening and sedimentation have appeared to be a reasonable treatment; in the latter part of May, as the stream flow is reduced, the sand filters are put into use in order to treat a substantial part of the wastes, and by that improved treatment the river is maintained in a relatively good condition. Still, later, as the flow in the river is reduced further, water is drawn from the reservoir, and parts of the unfiltered wastes are diluted with this flow in proportion to their quantity. During the period of hot weather of August and much reduced flow of the river in September, it is customary to take advantage of chemical treatment, and the wastes are treated with sulphate of alumina. The treated liquor is allowed to settle, and a part of the effluent is passed through the sand filters, the remainder being diluted with water from the reservoir and discharged directly into the river. On one occasion, during an extremely dry season when the supply of water became exhausted, sodium nitrate was added to the effluent to supply oxygen to the stream. This is rather an elaborate treatment, but it is far less costly than treating all the wastes throughout the year, in the manner required for the unusual conditions of the summer season.

The subject of separate systems of sewerage and drainage, presented by Mr. Dittoe, is of surpassing importance. About thirty years ago, a Massachusetts city with a population of approximately 20 000 built a separate system of sewers with extreme care. The pipe joints were made very tight, and the

* Cons. Engr. (Metcalf and Eddy), Boston, Mass.

system was apparently an excellent piece of workmanship. In recent times, measurements of the dry-weather flow at the treatment plant have shown less than 300 000 gal. in 24 hours. In time of storm, the flow has risen nearly to 3 000 000 gal. in 24 hours. A thorough investigation to ascertain whether it was possible to correct that condition has shown that, except in the case of one or two sewers which could be and have been improved, it is practically impossible to better the situation.

In a certain part of another city of relatively large size, separate sewers and drains were built by a commission independent of the City Council. On their completion, they were turned over to the Board of Works with an explanation, that roof drains were not to be connected with the sewers, and that sewage was not to be discharged into the storm drains. Within a short time, sewage was discharged into the drains, and water from the roofs was discharged into the separate sewers. It has been practically impossible to prevent these conditions, notwithstanding the fact that the city has a City Engineer who undoubtedly knows the needs of the case, but is impotent to remedy the conditions.

A number of similar cases might be mentioned, where separate systems of sewers have been so overburdened with the discharge from roofs and even from streets, where the street-water connections have been made by the city, that they have become partial, if not complete, failures. The problem is so serious that it is questionable in many cases whether separate systems of sewers should be constructed. Undoubtedly, separate systems will be constructed in the future, and it is to be hoped that means will be devised for using the sewers and the drains only for the purposes for which they were built.

About thirty years ago, separate sewers were built in a certain part of Worcester, Mass., and the care and diligence required to assure their proper use is a serious task. It may be of interest to mention the routine by which it has been accomplished. The connections between the sewers in the buildings are made by drain layers who are licensed by the Board of Aldermen, on the written approval of the engineer in charge of the sewerage system, and occasions have arisen when that approval has been withheld. Connections are made under the direction of the engineer in charge who inspects the work. The plumbers are licensed by the local Board of Health and, before they make any plumbing changes or construct new plumbing, are required to file a drawing showing what they propose to do. That drawing is filed with the local Board of Health which turns it over to the Sewer Department the approval of which is required before a permit to do the work is issued. After the plumber has completed the work, it is inspected by the Department of Health. That, however, was not sufficient, because where both sewers and drains are required and the pipe lines are carried to the inside of the cellar wall by the drain layer, the plumber has no means of ascertaining which is the sewer and which is the drain. Finally, it was decided that the hub of the drain pipe should be painted white and that of the sewer pipe remain its natural black color. Even this complicated control did not completely elimi-

nate wrong connections, made either by mistake or surreptitiously; and thus far it would seem practically impossible to prevent all such connections. House owners, without leave or license, will connect roof waters with sanitary pipes, and it is almost impossible to ascertain where such connections have been made. Mr. Dittoe has certainly presented a very serious question for consideration.

For many years, it has been the practice at Worcester to construct the separate system in the outlying districts, and parts of the central part of the city has been re-sewered according to the separate plan. The speaker knows of no changes in the combined system since 1900, and he does not know of any further plans for changes to the separate system.

J. FREDERICK JACKSON,* M. AM. SOC. C. E.—The speaker assumes that the object of this Symposium is to hasten the day when pollution will be removed from the streams in the United States. It has been stated that methods of sewage and sludge disposal should be adapted to the different classes of sewage being treated. As a general statement this is true, but engineers have not been successful in demonstrating this fact to the public at large, and it is still possible for any one with some new method to approach city officials having the final say in such matters and with a plausible story apparently convince them that they have the one panacea which will solve all sewage disposal problems.

The Industrial Wastes Board of Connecticut which was legislated out of office, was, strange to say, severely criticized, because it would not endorse a bill the provisions of which seemed so drastic as to make enforcement of them impossible.

One of the sensational papers in Connecticut contained a full-page article in which it was stated that a problem in stream pollution which the Industrial Wastes Board had had under investigation for three years and had failed to find a solution, had been solved in one week by a patented process controlled by a party outside the State. The reporter who prepared the article stated that while inspecting the plant, the patentee who was demonstrating the operation of the process, took a bottle of the wastes, added some ingredients, shook it up and down two or three times, and then holding it up to his view asked, "Are you satisfied?" He replied, "I am." Such ocular demonstrations of the solution of troubles of this kind apparently are effective with certain people.

The speaker believes that no solution of the problem of stream pollution will ever be accomplished in the United States, or elsewhere, until a strong public support is carefully and conscientiously built up before hand. There have been a number of remarkably careful and reliable investigations of stream pollution. What the public wants is a demonstration of some particular problem that has been solved or of some particular stream cleaned up. Investigations, no matter how thorough, apparently have little effect on legislatures. At the hearings before the Judiciary Committee in Connecticut, the Industrial Wastes Board was told, "investigations of stream pollution have

* Director, Bureau of San. Eng., State Dept. of Health, New Haven, Conn.

been going on in this State for thirty years, your particular Committee has been investigating the problem for four years, and you have spent $75 000. What have you accomplished? Nothing. We think that there have been investigations enough. What we want is the removal of the pollution from the streams." The bill which was under discussion provided that all pollution of the streams of Connecticut should cease by 1923, and this bill would have been passed by the Legislature except that, as one of the Judiciary Committee stated, the members of the Committee could not frame it so that it would be operative. If members of the Judiciary Committee cannot frame a bill to meet a proposition of this kind, how is it expected that engineers are going to do so? Because the engineers of the Industrial Wastes Board refused to set any time limit as to when they thought the pollution of the streams of the State should cease, the members of the Committee said, "Then you have failed."

As a result of experience in Connecticut, the speaker would call attention to the inadvisability of delaying too long the issuance of reports. In most of the important investigations in this country on stream pollution, the report is cold by the time it is published, and it seems that if some method could be provided whereby reports or portions of them could be issued while the problem is alive and before the public, it would be of great assistance in effecting a solution.

F. A. DALLYN,* ESQ.—One of the most encouraging signs in this discussion is the emphasis placed on the fact that sanitary engineers are now including biologists in their forces. The recognition of the part that biology is to play in the future of stream protection, in the operation of disposal plants, and in the degree of purification required, is the greatest step that has been taken by engineers in a long time, and it is hoped that a great deal of the time in future meetings of engineering societies will be left open to the researches of biologists. In his experience, the speaker has found no easier way of convincing industries of the facts relating to any situation than by putting them on a scientific basis. Nowadays, practically all large industries employ scientific experts; and when the matter is put before them in convincing terms which they understand, they appreciate the situation better than when engineers spoke in general terms of what they could do under such conditions.

W. F. WELLS,† ESQ.—As a biologist, the speaker will discuss briefly some phases of stream pollution, which are not necessarily engineering, but which are vitally connected with the problem of improving the streams in conserving the qualities of their waters. Mr. Jackson has brought up the point that although engineers have a great many data on the subject of the purification of wastes, when the public becomes interested in this subject as relating to the purity of water, it is at a loss to find any information which it can understand. In the last year or two, this question has become very important, because of the interest taken by those who are concerned in fish, commercially

* Provincial San. Engr., Toronto, Ont., Canada.
† Biologist and Sanitarian, State Conservation Comm., Albany, N. Y.

and for pleasure, as well as many other interests, such as bathing, gunning, etc., which are legitimate uses of these great resources of the people.

Recently, the speaker attended a conference in Washington, D. C., called by Herbert Hoover, M. Am. Soc. C. E., Secretary of Commerce, to consider problems brought about by the pollution of the coastal waters as affecting the fisheries. Incidentally, Senator Frelinghuysen, of New Jersey, pointed out the great importance of this subject, dwelling on it at considerable length as relating to the insurance business, namely, the higher rates on water-front property, which are brought about by oil pollution. Much has been heard about oil pollution recently. There are many phases and many angles connected with the problem of conserving the quality of the waters, and the people themselves are vitally interested, as shown whenever any one discusses the subject before those who are not particularly interested in the purification of wastes.

In fish conventions, the subject is given much attention, and, as Mr. Jackson has stated, the chances are that somebody will appear with a panacea for all the ills attendant on pollution; and the interest which these enlightened individuals take in the subject, and the ease with which they are convinced that there should be no such thing as pollution, is rather disheartening to one who is acquainted with the results which have attended such efforts in the past, and which are common knowledge among the Engineering Profession, but never get outside of it. The only way the question can be developed to the importance which it rightfully deserves, is by promoting in some manner public interest which is hungry for action of some sort, by uniting, as far as possible, the interests relating to the pollution of waters, by trying to get together those who are working on it and those who are interested in it, and by devising some means by which the knowledge that engineers have, may be given to the people who are concerned and whose resources are gradually being monopolized by individuals, industries, and particular communities. It is rather difficult to get such co-operation.

The speaker discussed the problem at the conference in Washington along that line, but his opinion did not receive much encouragement among officials, and he doubts whether it would receive the necessary attention among the Engineering Profession. However, the steps which are being taken, such as those mentioned by Professor Phelps, to develop a language of pollution—a technical language, terms in which the quality of waters can be measured and in which the purification of wastes can be stated—that will bring out the problem concretely, so that it can be handled, will tend, in the long run, to bring together those who are studying this subject, those working on studies of fish life, as well as those working along other lines. If they have some medium by which they can get into contact, ultimately the solution of stream pollution will be realized, and a great advance will be made not only with respect to general questions relating to the subject, but in the support that will be given the Engineering Profession in carrying out its essential work.

ALEXANDER POTTER,* ASSOC. M. AM. SOC. C. E.—It is impossible to overemphasize the importance of securing tight joints in house laterals and of

* Cons. Engr., New York City.

eliminating all waste water not intended to be cared for by a sanitary sewer system.

Engineers too frequently have labored faithfully on the construction of the street mains of a sanitary sewer system only to find their efforts defeated afterward by the careless and indifferent construction of house connections. When these conditions occur, it is almost impossible later to correct them, short of reconstruction of most of the house laterals. The speaker recalls an effort at Summit, N. J., some years ago, to eliminate the leakage in the system, which came very largely from the house connections. Carelessness in house-connection construction is not immediately noticeable in a gravity system, but when, as in the case of Summit, it became necessary to change from a gravity system to a pumping system which operated against a 200-ft. head, the elimination of all leakage was essential.

Although the exclusion of house leaders made some reduction in the quantity of waste, the bulk of the leakage came directly from the open joints of the laterals themselves. That much of the infiltration in sanitary sewers comes in through manhole covers is a popular conception, but the two or three days' lag in abnormal flow after a storm indicates a more indirect source.

Efforts made by municipal engineers to provide tight sewers have been thwarted, often purposely by town officials in their endeavor to make improper use of sanitary sewers, that is, for cellar drainage, roof leaders, yard drainage, and here and there a street catch-basin. The protest of the engineer and his pointing out the disastrous conditions which inevitably result from the improper use of house sanitary sewers, have little or no effect in many cases on the officials responsible for the maintenance of the sewer.

In one municipality with which the speaker was identified, the officials deliberately attempted to secure storm sewers by connecting leaders, yard, and cellar drains to the sanitary sewer system. Expostulation only brought the retort: "The sooner the sanitary sewer is used to capacity, the sooner we will get an adequate system". This argument might be valid if the house laterals could be transferred from the sanitary sewers to the storm sewers at will.

This disregard of the purposes for which the sewer is built causes overflow at low points and along outlet lines long before the normal capacity of the sewer has been reached. The resultant pollution is tolerated for years and is often greater in volume than that contributed from the legitimate overflow from combined sewers during heavy rains.

The speaker, knowing that these conditions exist and that they are next to impossible to remedy, has believed for many years that the adoption of the combined sewers with dry-weather interceptors is preferable to the strictly sanitary sewer. In many cases, only sufficient funds are available for sanitary sewers. Then, of course, the adoption of the separate system is logical and proper.

As far as the effect of the final disposal of the sewage is concerned, the disadvantage of the greater fluctuation both in the quantity and character of the sewage reaching the disposal plant and of the occasional discharge of

diluted sewage at storm overflows is offset by the advantage of excluding from the watercourse the filth accumulating in the streets during protracted dry spells, which exclusion cannot be affected when sanitary sewers are used.

The speaker is pleased to note a change in the policy of the health departments of many States in giving their approval to the use of the combined system, and it is hoped that this policy will have a wider range.

EDWARD S. RANKIN,* M. AM. SOC. C. E.—As another instance of the difficulties encountered by the engineer in preventing the improper use of sewers, the speaker's experience in Newark, N. J., may be of interest.

All the older sewers of Newark, which comprise about two-thirds of the city system, are built on the combined plan, but, in a number of the outlying sections, the separate system has been used during the last 20 years.

On the separate system, the average citizen cannot understand why he should not be allowed the same privileges as the citizen on the combined system, and be permitted to drain roof water into the sewer. For some years one of the members of the old Board of Works was a plumber who apparently held the same views. An investigation, a few years ago, disclosed a large number of leaders connected with these sanitary sewers, several of them having been made by this City Official.

Under the present commission form of government, this matter is entirely controlled by the Engineering Department, and the practice referred to has been almost eliminated.

S. JOHN SCACCIAFERRO,† JUN. AM. SOC. C. E.—The speaker was much interested in the paper presented by Mr. Pearse. With reference to the oxygen requirements of fish life, the results of some recent experiments performed under the direction of Professor C. L. Walker, Affiliate, Am. Soc. C. E., at Cornell University, for the New York Milk Conference, may be of interest. The experiments in general indicate that the ordinary milk waste is not toxic to fish, and is not detrimental to them except as it utilizes available oxygen; as long as the oxygen content is not reduced below 1 part per million, the fish will continue to live. The fish used were bass, trout, and the ordinary fish found in the lakes of Central New York State. During October, the trout and bass were kept in undiluted milk waste, both raw and after septic tank treatment, without any evident detrimental effect. The oxygen content, however, was about 4 parts per million.

Regarding the bio-chemical oxygen-demand test, the speaker agrees with Mr. Pearse's statement as to the usefulness and value of the test; he thinks, however, that the modified "excess oxygen" method developed by Messrs. H. B. Hommon and E. J. Theriault, (the method used in Mr. Pearse's experiments), requires further study, modification, and improvement. This statement is prompted by the results of some experiments made in the Sanitary Laboratory of the College of Civil Engineering, Cornell University in 1920, the procedure described by Mr. Hommon‡ being carefully followed. The wastes used were:

* Engr. in Chg., Bureau of Sewers, Newark, N. J.
† Civ. and San. Engr., Clifton, N. J.
‡ *Public Health Bulletin*, No. 97.

Milk-can and bottle washings before and after treatment in septic and Imhoff tanks, the effluents of these tanks after treatment in sand and percolating filters, cheddar cheese whey, and the sewage of Ithaca, N. Y., before and after septic tank treatment. Tests at 1, 2, 5, and 10-day incubations at 20° cent., were made of fifty-two series, each series consisting of three dilutions of a waste (except for the sand filter effluent, in which case the undiluted waste was used). Tap-water with an average initial oxygen content of 6.6 parts per million was used for dilution.

The results obtained were very discouraging, their outstanding features being a general inconsistency and the presence, at times, of greater amounts of dissolved oxygen on one day than on the day preceding. This last condition occurred frequently, despite the care taken to prevent any possible re-aeration or loss of iodine in the titrations. Due to the rather limited number of tests, and the wide variation in the results, no definite conclusions could be drawn. The results obtained, however, indicated that:

(1).—The "excess oxygen" method for the determination of the bio-chemical oxygen demand, although simple of performance, does not yield consistent results.

(2).—The bio-chemical oxygen demand is not independent of the dilution, as stated by Mr. Theriault,* but varies with the concentration of the waste, being higher for the lower concentrations.

(3).—No prediction of the probable demand at the longer incubation periods can be made from the results at the shorter periods (again failing to corroborate a statement of Mr. Theriault,* that from the results of the 5-day or possibly the 2-day incubation, the demand for the longer incubation periods could be predicted).

Despite the results obtained, the speaker still firmly believes that the test is important, and that further experiments are desirable, which will improve the "excess oxygen" method for the determination of the bio-chemical oxygen demand.

GLENN D. HOLMES,† M. AM. SOC. C. E.—The papers and discussions on Stream Pollution and Sewage Disposal have been of particular interest to the speaker as, at Syracuse, N. Y., these problems have been studied for some time for the purpose of improving the sanitary conditions of the watercourses throughout the city, and of Onondaga Lake into which these streams discharge.

The intercepting sewer system, on which construction was started some years ago, is practically completed. The watercourses which required deepening in order to permit interception of sewage from the lateral sewers without admitting back-water from the streams, have been improved and lined with concrete to insure permanency.

Tanks and fine screens of the types described by Mr. Hammond and Mr. Skinner, as well as many other processes, have been considered as methods of sewage treatment at Syracuse.

The sewage testing station, at which several types of settling tanks, filters, activated sludge units, grit-chambers, etc., were operated, furnished many data of pertinent value. These data together with those secured

* Public Health Report for May 7th, 1920.

† Chf. Engr., Intercepting Sewer Board, Syracuse, N. Y.

regarding sludge disposal, the volume, fluctuation of flow, and character of the sewage, as well as the character and condition of the water of the streams and lake, were of great assistance in reaching conclusions regarding the method of treatment best suited to the local conditions.

The method of treatment adopted includes degritting, coarse screening, and plain sedimentation in tanks equipped for continuous or frequent removal of sludge. The sludge is to be pumped about two miles to the lagoons of the Solvay Process Company and after intimate mixture with the waste liquors, will be precipitated and buried in the lime banks. These waste liquors are germicidal and are of sufficient volume to disinfect thoroughly more than ten times the quantity of sewage sludge which will be produced. The solids deposited from the industrial wastes are thirty to forty times greater in volume than the sludge solids, which insures complete and effective burial. This method of sludge disposal is unique and precludes the possibility of creating objectionable conditions in the vicinity of the lagoons, the treatment plant, or Onondaga Lake.

Before submitting the proposed method of treatment to the State Department of Health for approval (the approval has now been given), Harrison P. Eddy, M. Am. Soc. C. E., was asked to review the studies and conclusions and make such further investigations as he deemed necessary to enable him to report and recommend the method of treatment best suited to the sewage of Syracuse. It is gratifying to state that Mr. Eddy concurred in the recommendations.

In connection with the work at the testing station, an investigation was made to determine the relative effect of detention period and velocity of flow on the deposition of suspended solids. The detention period was found to be the controlling factor and velocities of flow within the limits of the experiments, which ranged between 12½ and 150 ft. per hour, had no effect on the clarification or removal of matter carried in suspension.

The percentage of removal is dependent to a large extent on the strength of the crude sewage, and this should be kept in mind when comparing or interpreting the results of treatment of different sewages. The term, "percentage of removal," is too frequently used without due consideration of the strength of the crude sewage.

A removal of 60% was obtained in ¾ hour with Syracuse sewage which contains an average of about 270 parts of suspended solids per million. The contributing factor in the attainment of this high efficiency, with the comparatively short detention period, was the frequent removal of the sludge, precluding septic action.

RUDOLPH HERING,* M. AM. SOC. C. E.—With reference to the discussion by Mr. Eddy, the speaker was asked, about 41 years ago, to report on the European sewerage systems for the National Board of Health, largely with reference to obtaining information regarding the separate system. Only two such systems were found in Europe, and these were for the Cities of Oxford and Reading in England. Continental engineers did not believe in the exclusion of rain water from sewers, much on the grounds stated by Mr. Eddy. In England,

* Cons. Engr., New York City.

some discouragement was felt even by the officials of the two cities mentioned, one of whom stated that there was trouble in preventing the discharge of rain water into sewer pipes, and also the surreptitious discharge of sewage into the storm drains. The City Engineer of Oxford, Mr. White, stated that if he had it to do over again, he would use the combined system which was common in most other European cities.

In his report, the speaker distinctly discriminated between these two systems with special reference to their application in the United States. It was found proper to place these systems on a par. The application of the separate system has large possibilities in the United States, as compared with Europe, and engineers should not recommend the combined system indiscriminately for all cities. Many communities could not afford the expense of the combined system and were satisfied to start with a system for sewage removal alone, with great benefit to their comfort and health. In New Orleans, La., a complete double system was recommended at the outset as it was found more economical than the combined system, because it cost less to pump the small volume of sewage into the Mississippi River, even at high water, and to let the large quantity of water from the heavy rainfalls flow in the other direction into Lake Pontchartrain at ocean level.

The speaker would recommend the separate system for many of the cities of the United States, particularly the smaller ones, for sanitary reasons, for otherwise they might not have any sewers until they could pay for the combined system.

About 35 years ago, the speaker was asked to study the Chicago sewage problem which had developed into a very serious situation. The question was whether to discharge the sewage into Lake Michigan, to purify it on land, or to discharge it into the Illinois River. At that time, little was known about bacteria. In fact, the first knowledge about bacteria in relation to sewage was acquired about the time the Chicago studies were being made. The available information, however, was not sufficient to aid in the solution of the problem.

In the United States, only the chemical analysis of sewage was generally reported, which by itself is not satisfactory. The speaker felt that the dilution question of disposal was an important one to consider for Chicago, not only on account of a possible lake disposal, but chiefly for the proposed channel which was to carry the diluted sewage to the Mississippi River. Information was available from a few places in Europe, particularly Paris, Hamburg, Dresden, Magdeburg, and a large number of cities in England. The best information, however, was from the work done on the Blackstone River in Massachusetts, and on the Desplaines River, into which the Chicago sewage was to be discharged, which information determined how much sewage could be put in running water without becoming objectionable.

All this information from Europe, Massachusetts, and Illinois was then plotted. It was astonishing to note the correspondence of these different data, and the indication from all of them that a dilution of from 2½ to 5 cu. ft. of water per sec. per 1 000 people appeared to be satisfactory.

As a result of this investigation, it was recommended for Chicago that there should be introduced into the Drainage Canal about 4 cu. ft. of water per sec. per 1 000 people sewering into the Canal. The speaker felt that he was not making a mistake in recommending an expenditure of $30 000 000 to have this channel built large enough to effect the dilution mentioned. In view of the slower velocity of water in the Chicago River and, consequently, the settlement of suspended sewage matter, a frequent removal by dredging was stipulated.

C. M. BAKER,* ESQ.—The abuse of sewers is a problem which cannot be over-emphasized. In practically all States it is the custom for the State boards of health to require the separate systems. In Wisconsin, there has been in operation for 7 or 8 years a system of plumbing inspection. This system was started before the Bureau of Sanitary Engineering was established.

The Department has a certain number of State inspectors, and all the plumbers in the State are required to secure State licenses. Through this organization a complete system has been built up, and the situation is fairly well under control.

Mr. Jackson is right when he states that the people want results in stream pollution rather than continued investigation as to the extent of the pollution.

The Chairman of the Conservation Commission of the State of Wisconsin has stated that at a National meeting of the representatives of the different conservation commissions of the States, he recommended that legislation be enacted prohibiting the discharge of polluting wastes into the streams —one of those suggestions for radical legislation.

The problem of industrial wastes has only been touched on, and very definite steps should be taken toward abating the existing polluted conditions. It seems to the speaker that possibly some of the funds expended in investigating existing conditions, the extent of the pollution, etc., might well be used for devising ways and means of eliminating or partly eliminating, at least, some of the most critical conditions with reference to pollution.

P. H. NORCROSS,† M. AM. SOC. C. E.—The speaker concurs in the statements, made by Mr. Hatton, regarding the necessity of disposing properly of the residual sludge from disposal plants. Experience has shown that the usual method of sludge disposal is primarily the cause of adverse criticism from laymen and the public at large.

Atlanta, Ga., was the first large city in the United States to construct a sewage treatment plant using Imhoff tanks for digesting sludge. The city now has three plants with capacities of 3 000 000, 5 000 000, and 6 000 000 gal. daily, respectively. The largest plant is subject to some of the abuses and troubles caused by the misuse of sewers, and, in addition, its capacity is overtaxed. The dumping of the sludge in low areas surrounding this plant has tended to create a nuisance and to invite litigation against the city.

LEONARD S. DOTEN,‡ M. AM. SOC. C. E. (by letter).—Since sewage is one of the chief causes of stream pollution, it has become customary to associate the

* State San. Engr., State Board of Health, Madison, Wis.
† Cons. Engr., Atlanta, Ga.
‡ Capt., Q. M. C., U. S. A., Chicago, Ill.

terms "stream pollution" and "sewage treatment", although they are antithical in meaning. All organic wastes, whether or not of human origin, industrial wastes, and the waste waters of mines, are the important contributing factors to the pollution of streams, lakes, and other natural bodies of water.

The introduction of water-carriage sewerage systems has greatly intensified the pollution of such bodies of water. For many years, it was the universal practice to discharge both storm water and domestic sewage into natural watercourses, rivers, lakes, or harbors. As a result, these bodies of water, in the vicinity of large centers of population, became greatly polluted, and, in some instances, very foul. Small streams have become so polluted as to be nothing less than open sewers. Such practice is no longer justified, as effective methods for the treatment of sewage and industrial wastes are now available. Notwithstanding the progress that has been made in the art of treating such wastes, writers of treatises on sewage disposal devote much space to discussions on "disposal by dilution." This term is synonymous with "stream pollution." So long as sanitary engineers sanction the practice of loading streams with organic wastes "to the limit of toleration," little progress will be made in the elimination of stream pollution. There is great need for reform in this matter.

Engineers and sanitarians should start a movement for clean streams. Undoubtedly, it will be a difficult task to educate the public to appreciate the higher standard and its advantages. The trend now seems favorable, although not as positive as it should be. The educational work should be along three important lines: public health, industrial, and economic.

It is essential that streams and lakes be protected against pollution, as in the future, all large public water supplies are, or must be, derived from surface sources. There will be an increasing demand for larger supplies, due to higher per capita rates of consumption, especially as the cities and towns become more populous. As a consequence, some of the streams which are now becoming more and more polluted by sewage and industrial wastes will ultimately be required for water supply and industrial purposes. With this condition confronting us and the trend of engineering opinion becoming more averse to the use of "reconstructed" water for domestic supplies, it is not difficult to see that the time is coming when the treatment of sewage and industrial wastes will become practically general in the United States.

Some of the States have adopted effective laws for the protection of streams against pollution. The State boards of health and other organizations having administrative authority to carry out these laws, should be aided by the Engineering Profession in every possible way.

Although there are several effective methods now in use for the treatment of sewage, the results are not in all cases satisfactory. The need is for standardization of practice, both in the design and the methods of operation of plants. Advancement in this work, like that in many other fields, must be made largely by perfecting details of existing processes or methods. Owing to the nature of the problem, it is extremely improbable that any process will be discovered, which will revolutionize the art.

Modern sewage disposal plants are not only "sewage treatment" plants, but can be operated so as to be in reality "sewage purification" plants, using the term, purification, in a relative sense, as it cannot be used in the absolute, even in water purification.

As generally understood to-day, sewage treatment accomplishes three objects: The removal of suspended matter, the reduction of that matter to a stable condition, and the oxidation of organic matter carried in solution. Treatment plants, therefore, should be designed so as to secure these results in the most satisfactory manner and at the least cost.

The sewage tanks now in use are highly efficient in the removal of suspended matter. It is not only possible to remove practically all settleable matter, but also a large percentage of the colloids.

The oxidation of organic matter in solution in the clarified liquid can be accomplished either by filters or by further tank treatment using the "activated sludge" principle.

As the non-settleable suspended organic matter (colloids) in sewage is a factor of considerable importance, even amounting to as much as 30% of the total matter in suspension, it is important that a large quantity of this matter be removed by tank treatment before the secondary, or oxidation, process is begun. Plain sedimentation, obviously, is not effective in the precipitation of colloidal matter. It is necessary, therefore, in treating sewage containing a large percentage of matter in this form, to use a type of tank in which the processes of "bacterial coagulation" and sedimentation may be carried out most completely. These are Nature's processes of clarification. A good illustration of the advantages of this method of treatment over plain sedimentation may be found in the clarification of laundry wastes. Plain sedimentation alone has no appreciable effect in lessening the turbidity of the liquid. Such wastes may be left in a quiescent condition for days without showing evidences of clarification. On the other hand, laundry wastes may be very effectually clarified by passage through a tank in which the biological processes are well established and conditions are favorable to the precipitation of the flocculated matter. These wastes may constitute 75%, or even more, of the total sewage without deleterious effects on the effluent, if a suitable range of detention periods is maintained.

JOHN A. GRIFFIN,* M. AM. SOC. C. E. (by letter).—The subject of stream pollution and sewage disposal is of particular interest to the writer at this time, in that the City of Los Angeles is confronted with the necessity of resorting to an emergency measure to cope with its overtaxed outfall sewer.

Los Angeles is one of the largest cities using a separate system of sewers, and the sewage is a relatively "strong" sewage. The diversion or disposal thereof into a relatively small creek which contains, in the dry season, a limited quantity of water, might tend to intensify the pollution of the creek. Practically, no water supply is derived from this creek and only a few wells are in proximity thereto. The level of the water in the creek is slightly lower than the ground-water in the surrounding areas, which would tend to drain

* City Engr., Los Angeles, Cal.

waters from the land and wells to the creek rather than pollute the wells from the stream. However, pollution to any marked degree would become objectionable, due to the fact that the course of the creek is through a rapidly growing suburb.

The isolation of the creek at other points than Culver City, makes its use, as an emergency measure, safe and justifiable, although it is well recognized that a dilution of from 2½ to 5 cu. ft. of water per sec. per 1 000 people sewered is necessary to prove satisfactory under ordinary conditions, yet the writer believes that a much smaller dilution factor can be resorted to with safety in this instance. If experience should demonstrate otherwise, it will only be necessary to discharge in the head-waters of this creek, sufficient fresh water from the Los Angeles domestic supply to bring the dilution factor to a point within the limit of safety.

The rapid growth of the city has brought about a condition that is causing much trouble. The outfall sewer to the sea, constructed in 1907, has become overtaxed to the extent that, in the dry-weather period, sewage has begun to flow out of the manholes into the streets and in the wet-weather period the discharge into the streets is enormous. This condition was anticipated nearly two years ago, and a bond issue was submitted to the people. This bond issue was defeated on June 7th, 1921.

With the overflow from the manholes into the public streets in a thickly populated section, came the apparent menace of epidemic and the necessity for immediate action. Although this overflow ultimately found its way into Ballona Creek over improved streets, it was necessary to provide a means to divert the surplus sewage to the creek without allowing it to flow along the streets. Permission to make this diversion has not been granted by the State Board of Health for the reasons previously mentioned, that is, the pollution of the small quantity of creek water, nor has sanction or permission been given for the use of the streets as natural channels to lead the sewage to the creek. In the absence of such authority, it was necessary, from a public health standpoint, to choose the lesser of two evils, and tap the outfall sewer near the head-waters of Ballona Creek to permit the surplus to flow directly thereinto without rising to the streets. This was done on January 4th, 1922, with the result that injunction suits have been filed by people down the creek.

The writer thinks that members of the Society may be interested in the peculiar position of the State Board of Health, that is, to grant a permit to use the creek for sewage disposal, even as an emergency measure, means the creating of a nuisance, with possible damage suits, whereas the ordering of the city not to utilize the creek would result in using the public streets as sewage channels, with the consequent menace to the health of a considerable population.

The time required to put through any semi-permanent relief will be more than two years. The outlook is not good for quick relief, and although the writer has recommended that no extensions to the sewer system be made and that house connections to existing sewers be disconnected and cesspools be resorted to until a permanent relief is provided, it is doubtful whether this program can be effectively executed, due to legal and other difficulties.

Bacteriological tests of the water of Ballona Creek, at Culver City, indicate no considerable pollution, even with raw sewage being discharged in the headwaters. When the sewage is fine screened and a small quantity of chlorine added, it is anticipated that no menace to health will exist. This meager emergency treatment will be carried on until permanent relief has been provided for the outfall. The time required for the sewage to flow from the proposed plant to Culver City is six hours and, under normal weather conditions, oxidation will be a material factor in its purification. Beyond Culver City, practically no nuisance will exist with ultimate disposal in the tide-waters at Del Rey Beach.

CLARENCE E. KEEFER,* JUN., AM. SOC. C. E. (by letter).—The paper by Mr. Dittoe should appeal to those in charge of the maintenance of sewerage systems. Baltimore, Md., is a striking example of a city with a separate system of sewers, where efforts have been made successfully by the city authorities to have these sewers put to their proper use. This condition is accomplished by co-operation between the Sewer Division and the Health Department of the city, and the Master Plumbers' Association.

The municipal laws require that, before the plumbing system of a house is connected to the city sewers, a permit must be obtained from the Health Department. The connection to the sewer is made by a master plumber and inspected by an authorized city employee. If it is found that there are any rain leaders emptying into the sanitary sewers, they are immediately ordered to be disconnected. In those parts of the city that are unsewered, the sewage is usually collected in cesspools. When sewers are built in such sections of the city, it is usually necessary to re-arrange the plumbing in the houses; and before this work is finally completed, inspections are made to see that it is done properly. Occasionally, it is brought to the attention of the Sewer Division that either cellar drains or rain leaders are connected to the sanitary sewers. Under such conditions, an investigation is made, and if the work was done by a master plumber, he is warned not to do so again, otherwise his license would be revoked.

In addition to laws governing the control of rain water entering sanitary sewers, there are other laws which make it illegal to dispose of gasoline, kerosene, germicides, or solid wastes into these sewers. As Mr. Dittoe has stated, more is required than the passing of laws governing the misuse of sewers. It is essential that these laws are enforced, and until this is done the best results will not usually be obtained.

One thing which should be provided for by cities is a law requiring property owners to connect their plumbing to the sewers. When a sewerage system is built, a few property owners, for one reason or another, will either defer making their connections to the sewers or fail to do so. In Baltimore, the property owners are notified when the sewers adjacent to their houses are completed, and they are given thirty days, with a reasonable extension of time, to connect their plumbing to these sewers. Usually, there is no trouble in getting them to do this. In case they should make any prolonged delay,

* Asst. Designing Engr., Sewer Div., Baltimore, Md.

however, the work is done by the city authorities, and the property owner is billed or assessed for the improvement made.

In his paper Mr. Hammond speaks of the use of separate sludge digestion tanks in the treatment of sewage. As is generally known, these tanks have been in use at Baltimore for about 10 or 12 years, and a great deal of information has been collected to date. However, much additional work will have to be done before the design of sludge digestion tanks is perfected. The first tanks built at Baltimore were rectangular in shape, each being 140 by 103 ft. in plan and from 13 ft. 6 in. to 15 ft. 6 in. deep. The sludge enters these tanks through a 12-in. cast-iron pipe at the top of the tanks. Three inlets are provided for each tank. On the opposite side from the inlet pipe, there are three outlets at the bottom of the tank. When these tanks were designed, it was thought that, as the sludge digested, it would settle to the bottom, while the undigested sludge would remain at the top. Until August, 1920, the reverse condition prevailed. Practically all the digested sludge collected at the top, in the form of a heavy scum which was fairly dry. In fact, at times it was sufficiently hard to bear the weight of a person in walking. On top of this scum, grass, weeds, and other vegetation grew to a height of a foot or more. The sludge as it entered the tank sank through this scum, and flowed under it directly to the outlets. The horizontal distance of flow was about 100 to 125 ft. No figures are available showing the time it took for the sludge to arrive at the outlet, but, in many cases, it was only partly digested. The moisture content of the scum was approximately 70%, whereas that of the sludge beneath was approximately 80 per cent. In order to move the sludge from these tanks through the 1 100 to 1 900 ft. of 12-in. cast-iron pipe line to the sludge drying beds, it was necessary to break up the scum with a stream of water.

In addition to these rectangular tanks, there are sixteen cylindrical tanks, each 38 ft. in diameter and 24 ft. 6 in. deep. Each tank has a capacity of 20 610 cu. ft., with inlet and outlet pipes, 8 in. in diameter. The inlet pipes are at the tops of the tanks, and the outlets are at the bottom. As in the rectangular tanks, the digested sludge forms a scum on the top, and the undigested sludge remains at the bottom. An additional sludge digestion tank has been built, in which various improvements over the old tanks have been embodied.

As the problem stands to date, it is possible to formulate certain principles pertaining to the design of sludge digestion tanks at the Baltimore plant. The depth of the tanks does not govern the degree and speed of sludge digestion. At present, designs are under way for three additional tanks which will have an approximate capacity of 650 000 cu. ft. In the future, it is likely that the tanks at Baltimore will have a depth varying from 15 to 20 ft. It is natural that the topography of the location of a sludge tank should be one feature governing the depth of these tanks. Where there is sufficient land available, and conditions warrant it, there is no reason why long shallow tanks, such as those at Birmingham, England, cannot be used.

One fact that has impressed itself on those connected with the operation of the sludge tanks at Baltimore is that the inlets should be as far away as

possible from the outlets, in order to prevent the short circuiting of the sludge, which condition has frequently occurred. One obvious and simple method of doing this is to construct in the tank a series of vertical baffles around which the sludge can flow to the outlet. The inlets should be designed so that the incoming sludge can enter below the surface of the sludge in the tanks. This is necessary, because if the incoming undigested sludge is allowed to spill through the air, disagreeable odors will be disseminated. In the last sludge tank built, the outlets were placed at various elevations so that there would be a possibility of drawing off the digested sludge at different elevations.

The capacities of sludge tanks should depend largely on the quantity of material to be handled. The cylindrical tanks, of which there are sixteen in Baltimore, are thought to be too small for the large plant there. The maximum size of sludge tanks will depend on the quantity of sludge to be handled. At Baltimore, it is not likely that tanks will be built having a capacity of more than 250 000 cu. ft. One necessary appurtenance to a sludge tank is a flushing water line so that water can be added, in case scum forms, and the scum broken.

In 1921, an unexpected condition occurred in the sludge digestion tanks at Baltimore. In one of the rectangular tanks, gas action which was prevalent over the entire surface of the tank took place, and, in a short time, all the scum had sunk. Sludge from this tank was immediately put into the other two digestion tanks, and, before cold weather began, the scum had settled to the bottom, and gassing was occurring in all three tanks. When this gassing started, there seemed to be an intimate mixture of the digested and the undigested sludge, with a consequent increase in digestion. One other condition noted was that this material flowed readily through the 12-in. cast-iron, pipe line to the drying beds, frequently without having to be pumped. Furthermore, it was no longer necessary to add water in order to break up the scum so that it would flow to the pump. Whether this gassing action will start again is problematical, but every effort will be made to study its causes and have it occur if possible. Much remains to be done on the investigation of sludge digestion, in fact, various experiments have been conducted already on sludge digestion at Baltimore.

WATER SUPPLY AND WATER PURIFICATION*

A SYMPOSIUM

By Messrs. George C. Whipple, Allen Hazen, C. A. Emerson, Jr., C.-E. A. Winslow, C. A. Holmquist, Robert Spurr Weston and Samuel A. Greeley.

With Discussion by Messrs. Louis L. Tribus, G. F. Catlett, John R. Baylis, P. H. Norcross, H. Malcolm Pirnie, C. M. Baker, George W. Simons, Jr., M. N. Baker, H. N. Bundesen, and Charles Haydock.

* Presented at the meeting of November 17th, 1921.

HISTORY OF WATER PURIFICATION

By George C. Whipple,* M. Am. Soc. C. E.

The history of water purification in the United States is intimately connected with the general movement to improve sanitation and public health, as well as with the rise of modern science. No excuse, therefore, is necessary for referring to these subjects by way of introduction.

The great sanitary awakening occurred in England about the middle of the Nineteenth Century. Following the social uplift, sometimes called the New Humanity, which occurred in the Twenties and Thirties, came the sanitary surveys of Sir Robert Rawlinson, the public health activities of Sir John Simon, the statistical studies of Edwin Chadwick, and, in the Forties, the medical investigations of Dr. Southward Smith. The English public health system dates from 1848. The new public health inspiration crossed the Atlantic and, in the late Forties, occurred the investigations of Lemuel Shattuck, which culminated in that remarkable document, the Report of the Massachusetts Sanitary Commission of 1850.† The movement, however, became side-tracked in the United States, because more important issues were before the public.

During and after the Civil War, the problems of sanitation were attacked anew. A Citizens' Association made an investigation of the sanitary condition of New York City in 1865. The Massachusetts State Board of Health was established in 1869. The American Association of Public Health was founded in 1872. Meantime, a new demand for public health measures had arisen. The Civil War had left an aftermath of disease. In particular, typhoid fever which had been so prevalent in the armies, was scattered throughout the country. Many a returned soldier had become unwittingly a typhoid carrier, and the typhoid fever death rates were very high. In Boston, Mass., from 1855 to 1860, the typhoid rates were between 40 and 50 per 100 000; during the Sixties, they were above 60 for one-third of the time; in 1872, the rate was 86 per 100 000—high figures for a city like Boston. The rates in other cities were equally high, sometimes much higher.

It should be remembered, also, that it was during the last half of the Nineteenth Century that modern science began its remarkable development. Several events marked the new era, the most important perhaps being the publication of Darwin's "Origin of Species" in 1859. With it, came the wide application of the inductive system of reasoning, of the experimental method. All sciences went forward as a result of the impetus given by the new ideas. In the late Sixties and early Seventies, Pasteur made his great discoveries. These were followed by the work of Koch and others in the Eighties, and the science of bacteriology soon arose. The experimental method was at once applied to the field of sanitation, including water purification. Although filtration had been used for a part of the London supply as early as 1829, the benefits of the process were not appreciated, nor its action fully understood for many years after that date. Following a cholera epidemic in 1839,

* Prof., San. Eng., Harvard Univ., Cambridge, Mass.

† Long unavailable, but now reprinted in "State Sanitation", Harvard University Press.

filtration was extended rapidly, and, in 1855, was made compulsory for the London Metropolitan District. It was the rise of the science of bacteriology and all that went with it, that caused the modern development of this greatest of the sanitary arts—the art of water purification.

Fifty years ago, the quality of the existing water supplies in the United States was low, judged by modern standards. Clearness and freedom from color, taste, and odor were the ruling standards, and even these were often not complied with. In some regions, a great deal of attention was being given to lead poisoning and to hardness. Water analysis was confined to the mineral constituents. The germ theory of the transmission of disease through the agency of sewage polluted water had not arisen. In the United States, water purification was practically an unknown art.

Beginnings of Filtration in the United States.—In 1866, the late James B. Kirkwood, Past-President, Am. Soc. C. E., was sent to Europe by the city authorities of St. Louis, Mo., to study the new methods which had been coming into use in England and Germany, for besides the London filters there were, at this time, filters in many of the English, and in most of the large German, cities. Kirkwood's report, the first important document on filtration published in the United States, may be said to mark the beginning of the history of water purification in America. His plan for filtering the muddy water of the Mississippi River, which was based on his European observations, was not adopted by the municipal authorities of St. Louis. It was fortunate that the plant was not built, for later studies of the filtration of such waters have shown that it certainly would have failed. Several other filters, however, were built as a result of his report, notably the filter at Poughkeepsie, N. Y., which was constructed in 1873 to clarify the water of the Hudson River. This filter was the most successful of several which were built about that time.

In 1878, Professor William Ripley Nichols went to Europe to study water purification for the Massachusetts State Board of Health and his report was published in the Annual Report of the Board of that year. Five years later, his notable book on "Water Supply" was issued, in which he discussed not only the problem of filtration, but that of tastes and odors as related to the algæ. In many ways, this book was a pioneer in its field. For a considerable time the center of interest in matters connected with water purification was in Massachusetts. In 1887, the State Board of Health established an experiment station at Lawrence, and the purification of water as well as the treatment of sewage was studied from all possible angles, engineers, chemists, and biologists contributing to the investigations. The experiments were made on the relatively clear but polluted water of the Merrimac River. Some of the men prominent in connection with this work were the late Hiram F. Mills, Hon. M. Am. Soc. C. E., the late Frederic P. Stearns, Past-President, Am. Soc. C. E., Allen Hazen and George W. Fuller, Members, Am. Soc. C. E., H. W. Clark, Edwin O. Jordan, Mrs. Ellen H. Richards, Professor Thomas M. Drown, and Professor William T. Sedgwick, the last two acting in an advisory capacity. This was the first important scientific study of the subject of water purification in America, and its results did much to develop the art.

While these experiments were under way, a notable epidemic of typhoid fever swept down the Merrimac Valley and included the City of Lawrence which took its water supply from the river. It soon became evident that a filter was needed, and, in 1893, a sand filter designed by Mr. Mills was put into operation. This filter was built as a single bed without a roof and involved certain complicated arrangements of coarse and fine sand, ideas which have not been followed in other plants; in fact, the filter has been largely rebuilt in recent years. This filter became a great object lesson to the country, as it showed conclusively that polluted water could be made safe for drinking. It was a practical demonstration of the ideas which had been developed at the Lawrence Experiment Station.

After his work at Lawrence and after conducting experiments at the World's Fair in Chicago, Ill., Mr. Hazen spent a year in Europe studying foreign practice, and from this experience came his book on "Filtration", which for a generation was the leading authority on the subject. Unfortunately, it is now out of print.

Meanwhile, filtration had been developing in another direction, in regions of the country where the water supplies were muddy. In 1883, the late Charles Hermany, Past-President, Am. Soc. C. E., conducted some experiments in the filtration of the water supply at Louisville, Ky. In 1884, Alpheus Hyatt obtained a patent on the use of sulphate of alumina as a coagulant, and in the same year a mechanical filter in which such a coagulant was used, was built at Somerville, N. J. Although mechanical filters had previously been used for clarifying water for industrial purposes, this was the first application of the method to a public water supply. The name of Professor Albert R. Leeds should be remembered in connection with the early development of this process, as he was its inventor. A mechanical filter was built for the water supply of New Orleans, La., but failed to meet the requirements and was removed at great loss to the promoting company. Several other installations were made in different parts of the country. Some of these early mechanical filters gave fairly good results, but others failed. It became evident that the process was not only useful but necessary for the purification of muddy waters, and also that engineers had not learned how to utilize it successfully. Then, Science came to the rescue. In 1893, the late Edmund B. Weston, M. Am. Soc. C. E., made some tests of mechanical filters for the City of Providence, R. I., which should be remembered as the first carefully conducted tests with this type of filtration. From 1895 to 1897, Mr. Hermany again studied the problem of filtration, this time with the assistance of Mr. George W. Fuller and a corps of engineers, chemists, and bacteriologists, acting for the Louisville Water Company and several companies interested in the construction of mechanical filters. These experiments, conducted on the water of the Ohio River, resulted in a notable report published by Mr. Fuller. The Louisville experiments were devoted to a study of the theory of the filtration of clay-bearing waters and the use of coagulation and sedimentation in connection with mechanical filtration. The principles thus established have served as the basis of the mechanical filters which have

since been constructed in the United States. Various devices used in mechanical filtration were also tested at Louisville and their weaknesses pointed out.

The experiments at Lawrence and Louisville demonstrated the fact that different kinds of waters require different methods of purification; that although slow sand filtration can be used successfully with a relatively clear water like that of the Merrimac River, at Lawrence, coagulation must accompany filtration in the case of muddy waters, such as those of the Ohio and Mississippi Rivers. With this thought in mind there followed a series of tests in different parts of the country. At Pittsburgh, Pa., Mr. Hazen conducted experiments to compare the relative advantages of sand and mechanical filtration for the water of the Allegheny River, and his report thereon was published in 1899. Mr. Fuller made further experiments in mechanical filtration in Cincinnati, Ohio, in 1898, and experiments were also made at Washington, D. C., Superior, Wis., New Orleans, La., Philadelphia, Pa., Reading, Pa., Boston, and elsewhere. It was a time of experimentation, and much of this experimental work was done by men who had received their early training in Massachusetts.

Progress of Filtration.—The first large slow sand filter to be constructed after that built at Lawrence, was designed by Mr. Hazen for the City of Albany, N. Y., to treat the water of the Hudson River. This filter was put into service in 1899. It differed in several respects from that at Lawrence, especially by having a masonry cover, experience having already shown that cold weather interfered with the operation of open filters like those at Poughkeepsie and Lawrence. The Albany filter has served in many ways as a model for the sand filters which have since been constructed in the United States, such as those at Washington, D. C., Philadelphia, Pa., Providence, R. I., and many other cities.

The first important mechanical filter to be constructed along modern lines was that of the East Jersey Water Company, at Little Falls, N. J., which was put into service in 1902 to purify the water of the Passaic River. As long as the basic Hyatt patent was in force, the construction of mechanical filters had been confined chiefly to those built by private companies; after the expiration of this patent in 1901, however, the art of mechanical filtration advanced rapidly. In 1904, a large mechanical filter was built for the Hackensack Water Company in New Jersey, and many others followed.

It will be seen, therefore, that it was just about the beginning of the Twentieth Century when water purification in the United States really began to advance as a practical measure. The last decade of the Nineteenth Century had been one of experimentation. The work done by the chemists and bacteriologists was to be taken up by the engineers and pushed rapidly.

Since 1900, there has been a great increase in the use of filtration. In 1870, practically no filtered water was in use in this country. In 1880, 30 000 people in cities having populations of more than 2 500 were using filtered water. In 1890, this number was increased to 310 000; in 1900, to 1 860 000; in 1910, to 10 805 000; and, in 1920, to at least 20 000 000. At the present time, more than one-third of the people living in cities which contain

2 500 or more inhabitants are using water which has been filtered. The number of filters in the country is probably not far from 800.

Present Problems.—Water purification would not be a growing art unless there was new work ahead, and unless new problems were being studied. A survey of the situation reveals some interesting facts and tendencies.

In the first place, not all the water supplies of the country are being adequately protected. There are still some places where grossly polluted water is being distributed to the people, although year by year these places are decreasing in number. There are many places where the water is reasonably safe, but is not attractive at all times for one reason or another. Fifty years ago, and even twenty-five years ago, the New England water supplies were on the whole better in quality than those in other parts of the country, but, to-day, filtration has become so common in regions where the streams are naturally muddy that the New England supplies, few of which are filtered, suffer in comparison with filtered waters elsewhere, in so far as the quality of attractiveness is concerned. In New England, the policy of utilizing natural storage and preventing pollution in all possible ways was wisely adopted, but these measures have their limits and, with the increasing populations, the filtration of surface waters is likely to become universal; it may even be required by law.

There are many places in the United States where disinfection has been adopted without filtration or in place of adequate attempts to prevent pollution. Gradually, the weakness of this policy is being discovered. Disinfection is very cheap, but cheap disinfection does not accomplish what filtration does, and it should not be accepted as a substitute for vigilance in protecting a water supply against pollution.

Since the typhoid fever rates of the country have been greatly reduced, consumers are thinking less about the dangers of their water supplies and more about its physical appearance, about its corrosive properties, and about its fitness for industrial uses, that is, they are seeking refinements. Thus, a new class of problems, such as water softening with the use of lime and soda, or with permutit, the removal of iron and manganese, and the neutralization of acidity, is receiving the attention of water chemists.

Many of the filters built 10 and 20 years ago have been in use long enough to show defects in practical operation, and experience has indicated wherein changes can be made to avoid depreciation, reduce repair costs, save money in operation, and get better results. Filter designs are slowly being modified as a result of these findings. It is natural that, at the time of building these filters, officials should give the greatest attention to construction cost, but, as time goes on, it is the costs of operation which are scrutinized. The usual lower first cost of mechanical filters is a reason why it is sometimes easier to induce cities to construct that type of filter rather than a slow sand filter which usually costs more to build but less to operate. Higher operating costs, however, make mechanical filters less popular after a term of years. The economics of filter operation can now be studied more carefully than was possible twenty-five years ago, and this is a phase of the subject which is likely to receive increasing attention.

Methods of testing the performance of filters by the use of analyses have not changed greatly in twenty-five years. In the early days, stress was laid on the percentage removal of bacteria, color, turbidity, and organic matter. Tests were made to show what the filter was able to do. Engineers now are more interested in knowing what the filter actually does, and the analyses must serve as a test of the filter operator as well as the filter itself. When discussing water analyses, Dr. Drown used to say that "a state of change is a state of danger." Now, the principle is emphasized that a state of irregularity is a state of danger. Filters are wanted, which operate so as to give a uniform product from day to day and hour to hour. Therefore, attention is being given to the application of the mathematical theories of probability to filter records. There are great possibilities in this study, but they are appreciated at present by only a few engineers.

A new impetus is being given to many of the problems of water purification by the use of new and simple methods of determining the true acidity of water in terms of the hydrogen ion concentration. This and other methods of physical chemistry are likely to clarify many ideas in regard to problems of coagulation, corrosion, disinfection, and the growth of algæ.

Bacteriological tests of water have never been as definite as chemical tests. The difficulties have been partly analytical and partly statistical. The test for *B. coli* has been largely, and, on the whole, successfully, used; but it has many shortcomings. The use of tests for determining the presence of spore-forming organisms is under discussion, so that water bacteriologists as well as water chemists are active in their researches.

In the field of vital statistics new ideas are also coming to the front. The typhoid fever death rates are becoming so low that they can no longer be regarded as sufficient to measure the healthfulness of a water supply. The so-called Mills-Reincke theorem, which held that for every death from water-borne typhoid fever there were several deaths from other diseases due to water, has been found not to hold generally, although there is much truth in it. Polluted water may cause sickness of one kind or another, which does not find record in the vital statistics of the community. Some more careful measure of the effect of water on the health of the community is urgently needed.

Thus, it is seen that there are activities among engineers, chemists, biologists, and statisticians in the field of water purification, a fact which is full of promise.

RECENT DEVELOPMENTS IN WATER FILTRATION

By Allen Hazen,* M. Am. Soc. C. E.

A Dutch author has grouped all waters in public water supplies in two classes, namely, aggressive and quiet. He defined aggressive waters as those having a tendency to attack and corrode the iron pipes through which they flow and other metal fixtures with which they come in contact. Quiet waters do not have this tendency to attack metals.

Aggressive water is very troublesome in a distribution system. The treatment of water so as to purify it adequately without making it aggressive is one of the most difficult problems at present. Water leaving the filter may be of good color, show a good bacterial test, be free from turbidity and other injurious elements, and may appear to be in all respects suitable for public water supply, but if it is aggressive, it will not be satisfactory to the users. An aggressive water attacks and tuberculates the pipes, reduces their carrying capacity, and will ultimately destroy them. In doing this, however, some of the iron of the pipes is taken up, and it is this iron which makes the water objectionable. The iron taken up causes a supplementary coagulation in the water, and the floc formed in this way settles out where the velocity of flow is low. This deposit is a dirty mud which remains on the bottom of the pipes until the flow is increased sufficiently to move it. It then moves forward with the flow and makes the water dirty and disagreeable, giving just cause for complaint.

There is another condition similar to this, which is frequently associated with it. Water which has received chemical treatment before filtration, frequently passes the filter before the chemical reactions are altogether complete. Such water leaving the filter contains a small quantity of coagulant which separates in the pipes and produces the same conditions as those caused by the iron taken up from the pipes. Probably this condition of incomplete chemical reaction at the time of filtration is found mainly with aggressive waters. At any rate, the two conditions produce similar results and frequently are found together, in which case, the resulting conditions are much worse than they would be otherwise.

The question of why some waters are aggressive and others quiet is presented. Twenty years ago, chemists would have stated that it was, first, a matter of alkalinity, and carbonic acid would have been mentioned as a second important contributing factor. Alkalinity and carbonic acid really have something to do with aggressive qualities, but all the conditions cannot be accounted for by them. Other explanations must be found. Recently, new methods of testing have been originated. The theory of "ions" has been developed, and it is thought by some who have been studying the matter, that a connection between the "ions" and the aggressive qualities of waters can be traced. Tests based on these new ideas have been devised, and have been applied for the first time quite recently, and there now seems to be some hope of a method of ascertaining more definitely when water will be quiet and

* Cons. Engr. (Hazen, Whipple and Fuller), New York City.

when it will be aggressive. Knowledge comes first, and when engineers understand better why waters are aggressive, it will be easier to find methods of treating them so as to keep them quiet.

A great deal is known in a practical way as to which waters are aggressive and give trouble because of their aggressiveness. The waters of the Great Lakes are almost always quiet and can be filtered and purified in a manner to keep them so. In the Mississippi Valley, from the Alleghanies to the Rockies, the surface waters used for public water supplies are generally hard, and can be handled, by carefully managed treatments, so that the resulting products will be reasonably quiet. Thus, through all that broad expanse of country, the problem of aggressive waters is much less important and difficult.

Soft waters are frequent nearer the coasts, both East and West, and they often carry organic matters of vegetable origin. These waters are much more apt to be aggressive, and it is with them that the greatest practical difficulties have been met. Experience shows that it is difficult to treat some of these waters by methods otherwise effective, which will clear them up and make them satisfactory for public water supplies, and which will leave them quiet. Many of these waters require chemical treatment, and no other means of adequately purifying them has been found, but in some way this chemical treatment stirs up the sleeping ingredients of the water and makes them aggressive.

Decolorizing yellow swamp waters by means of chemicals seems particularly difficult of accomplishment without bringing out the aggressive qualities. The question of color is mainly one of esthetics, and it may fairly be asked whether the increase in aggressive qualities in decolorizing water does not largely or entirely offset the advantage gained, and whether it would not be wiser in some cases to get along with less decolorization.

The chemical treatment of water introduced many years ago had numerous advantages and came to be widely used. Many waters, however, can be treated with entire success without chemical treatment. This depends on the character of the water, and on what is to be removed from it. Chemical treatments may have been used in some cases where it would have been better to have avoided them. Decision to use them may have rested on consideration of all the other factors in the case. When the development of aggressive qualities is also taken into account, perhaps, in some cases, the decision would have been better made the other way.

It may be mentioned that one industrial establishment is now constructing a plant for the purification of water without the use of chemicals. Formerly, chemically treated water was used, and experience with it has indicated the difficulty of furnishing water sufficiently quiet so that it would not damage the delicate products of this particular establishment.

The question of arranging all the treatments of public water supplies so as to keep them always quiet is one of the most interesting and important aspects of water purification.

INTERFERENCE WITH WATER FILTRATION PLANT OPERATION BY WASTES FROM BY-PRODUCT COKE OVENS AND GAS-WORKS

By C. A. Emerson, Jr.,* M. Am. Soc. C. E.

The discharge of liquid wastes from by-product coke ovens and commercial gas plants into streams and lakes from which water supplies are taken, has become, during the past few years, a matter of grave concern to many medium sized and several of the largest cities, due to the disagreeable tastes and odors which these wastes impart to the water.

As the superiority of by-product coke ovens over the old beehive type is now fully established, it follows that the number and capacity of these installations will undoubtedly increase. By-product ovens of necessity must be located reasonably close to a steel works or a large municipality in order to secure a ready market for the gas given off during the coking of the coal, and, therefore, it is almost certain that interference with surface water supplies will also increase, if proper precautions are not taken.

The wastes from the tar separators, the ammonia, benzol, and naphthalene stills of by-product coke ovens, together with the sludge removed from the various gas and oil mains throughout the plant, impart a characteristic taste to river water. This taste may persist for days and, after transportation for many miles, be noticeable in the effluent from well operated, water filtration plants of modern types, taking their raw water supply from the stream. The application of chlorine, even in the minute quantities used for water supply treatment, seems to accentuate rather than diminish these taste-producing characteristics. Under favorable conditions, dilutions as great as several million parts of chlorinated water to one of the wastes have failed to cause complete disappearance of this taste.

Fortunately, the remedy for this pollution lies within the works, and consists simply of evaporation of the contaminated liquid wastes by using them for quenching or cooling the glowing coke taken from the ovens. The waste water which is not turned into a cloud of steam, but passes through the quenching platform, is intercepted in settling basins and again used for quenching. In all the plants coming under the speaker's observation, the water requirements for coke quenching have exceeded the volume of contaminated wastes, so that this remedy has not worked any hardship on the owners.

That the remedy is effective is evidenced by the fact that the largest by-product coke-oven installation in the world is operating on the Monongahela River, ten miles above the intake of a municipal water-works, without causing contamination of the supply. Take another stream in Pennsylvania as an example: The installation of appliances for using liquid wastes from stills for quenching the coke silenced complaints among the consumers of filtered water in several municipalities along the stream about seventy miles below the works. That the method is beyond the experimental stage is indicated by the fact that

* Chf. Engr., State Dept. of Health, Harrisburg, Pa.

it has been in successful use at numerous plants for several years and that, in some instances, the volume of liquid wastes evaporated is in excess of 1 000 000 gal. daily.

Interference with water supplies by the wastes from plants producing water gas for illuminating and power purposes has been noticeable in different parts of the United States. Definite evidence that the tastes due to these wastes are as persistent, or that they can be detected in as high dilutions, as those from by-product coke ovens, seems to be lacking. There is, however, sufficient evidence to justify the statement that the raw wastes from these plants, when subjected to dilutions available in rivers of considerable size, will cause tastes after transportation by the stream for several miles. With these wastes, also, the taste-producing characteristics are accentuated by chlorination of the drinking water taken from the stream.

Aeration of the raw water, thus contaminated, prior to filtration seems to be of considerable value, but in this case, again, a certain and effective remedy can be developed at the gas-works. It has been found that the installation of settling and skimming basins to permit the removal of the greater portions of the heavier tars and the light floating oils, with the circulation of the basin effluent for re-use in the "gas scrubbers", will not only materially decrease the proportion of active taste-producing constituents, but will reduce the volume of wastes reaching the stream to a small fraction of that which occurred before the water was re-circulated through the plant. In addition, the company recovers marketable materials to offset the cost of operating the circulating pumps.

In one instance coming to the speaker's attention recently, it was deemed advisable to require the gas company to go even further, and to keep all liquid wastes from the stream. This company, by the use of settling basins and circulating pumps, had decreased the volume of wastes from 50 000 to about 5 000 gal. per day. This waste was high in turbidity, had an oily appearance, and was brown in color, but it was found that after it had been strained through a layer of coke breeze, about 6 or 8 in. in thickness, and had received a moderate application of ferrous sulphate solution, it could be passed through a small sand filter at a rate of about 400 000 gal. per acre daily and then become a satisfactory boiler water. Contrary to all expectations, the sand filters did not clog immediately, but were operated for runs of several days' duration between scrapings.

Occasionally, there has been doubt as to legal authority to require abatement of the class of pollutions described, as the laws controlling stream pollution due to the discharge of industrial wastes are weak and vague in many States; however, instances are recorded where applications for restraining injunctions have been granted under the broad general rights of lower riparian ownership and, accordingly, it is believed that in a surprisingly large number of cases definite obligations can be imposed on owners of such works to prevent troublesome stream pollution.

RECENT PROGRESS IN THE REDUCTION OF THE TYPHOID DEATH RATE AND ITS SIGNIFICANCE

By C.-E. A. Winslow,* Esq.

It seems worth while to call attention to the remarkable progess which has been made in the reduction of the typhoid death rate since George A. Johnson, M. Am. Soc. C. E., presented his admirable review of "The Typhoid Toll" before the American Water Works Association, five years ago.† One may go back perhaps even a little farther with profit and take as a basis for comparison the statistics for certain large cities for the period, 1898-1908, presented by Mr. G. R. Taylor.

TABLE 1.—Typhoid Statistics of Cities of the United States, 1898-1908 and 1917-1919.

City and State.	Typhoid death rate per 100 000 population. Average, 1898-1908*.	Typhoid Death Rate per 100 000 Population for 1917, 1918, 1919 (United States Mortality Statistics):

* "A Classification and Study of the Typhoid Statistics of the Cities of the United States", by G. R. Taylor.

The statistics for this period are compared with those for 1917, 1918, and 1919, in Table 1, and Table 2 shows the distribution of these cities in the two periods, by their grouping in regard to typhoid mortality. It will be

* Professor of Public Health, Yale School of Medicine, New Haven, Conn.

† *Journal*, Am. Water Works Assoc., Vol. 3 (1916), p. 249.

noted that in 1898-1908, each of the thirty-five cities had a death rate of more than 15 per 100 000, and that seventeen, or practically one-half of them, had a rate of 30 or more. In the last three years, however, only one city of the same thirty-five has had rates of more than 15, only six have had rates of more than 10, while more than one-third have had rates below 5 per 100 000. This is a truly remarkable achievement and one which is not confined to the cities in question, but which is general throughout the United States.

TABLE 2.—Death Rate from Typhoid Fever in Certain Large Cities of the United States.

Distributed by Classes.

Number of cities in each class, 1898-1908.....	0	0	0	10	8	6	5	5	1
Number of cities in each class, 1917-1919.....	12	17	4	1	1	....	....	....	....

In Table 3 are presented the data for the gradually expanding area of the registration States, which show that for this unit of area the typhoid rate has dropped in thirty years to less than one-third of its 1890 value. The actual accomplishment is even more striking than such a tabulation would indicate for, as the registration area has increased, it has tended to include more and more cities with relatively primitive sanitary organization. Table 4 shows the figures for the registration States as the area existed in 1900, and it will be seen that when the same States are compared, which had a rate of 25.4 in 1900, the rate had fallen to 6.5 in 1916-19, a reduction of nearly 75 per cent.

TABLE 3.—Death Rate per 100 000 Population from Typhoid Fever in the Expanding Registration States for Different Periods, by Cities and by Rural Areas, 1890–1919.

Place.	Period Considered:					
	1890.	1900.	1901-05.	1906-10.	1911-15.	1916-19.
Registration States.....	36.0	25.4	24.9	24.6	16.3	11.9
Cities.....	39.0	25.3	24.5	25.3	14.8*	9.2*
Rural areas	31.4	25.5	25.4	23.8	17.8	13.7

*Municipalities of 10 000 or more inhabitants in 1910.

Such results are highly gratifying, but the speaker would like to utter a word of caution relative to the claims any one may be inclined to make in regard to the factors which have brought about this reduction. One is naturally tempted, when the figures for such cities as Pittsburgh, Pa., are

examined and where the reduction in the typhoid death rate was from 116.9 (1898-1908) to 6.5 (1919), to claim all the credit for the water-works engineer, but a little consideration will show that there are other powerful forces at work.

TABLE 4.—DEATH RATE PER 100 000 POPULATION FROM TYPHOID FEVER IN THE ORIGINAL REGISTRATION STATES FOR DIFFERENT PERIODS, BY CITIES AND BY RURAL AREAS, 1900–1919.

† Connecticut, District of Columbia, Maine, Massachusetts, Michigan, New Hampshire, New Jersey, New York, Rhode Island, Vermont.

The data for the expanding registration area presented in Table 3 would suggest that the typhoid death rate has fallen much faster in cities than in rural areas, but this conclusion is wholly fallacious, for the expanding registration area has tended to increase the proportion of sub-standard rural areas much faster than the proportion of sub-standard urban areas. If the rural and urban changes in the death rate in the original registration States of 1900 are compared, it will be found that the reverse condition obtains; in other words, when the same group of cities is considered, the rural death rate has decreased more markedly than the death rate in urban communities. This fact alone is sufficient to indicate the complex nature of the problem, since improvements in water supplies have certainly been vastly more effective in cities than in rural districts. The improvement in privy sanitation, the war against the fly, the pasteurization of milk, and, since the World War, the use of typhoid vaccine, have each played an important part in the conquest of typhoid fever, and there is glory enough for all in the fact that at last the typhoid statistics of the United States can be compared with those of Europe without the sensation of humiliation.

THE EFFECT OF WATER PURIFICATION AND IMPROVEMENTS IN WATER SUPPLIES ON THE TYPHOID FEVER DEATH RATE IN NEW YORK STATE

By C. A. Holmquist,* Esq.

Before discussing the reduction of typhoid fever, due to improvements in water supplies, the speaker will review briefly the part played by the New York State Department of Health, more particularly the Division of Sanitary Engineering, now the Division of Sanitation, in improving the public water supplies of the State through its general supervision over their sanitary quality. The first State Board of Health of New York was organized in 1880, under the provisions of the Public Health Law. This Board consisted of nine members, nearly all of whom were physicians.

In 1901, the State Board of Health was abolished, and a State Department of Health, with a commissioner at its head, was created. In 1906, the Division of Sanitary Engineering was established. Up to that time, relatively little attention had been paid to public water supplies. Engineers were employed from time to time to advise the Board and to investigate matters pertaining to sewerage and sewage disposal, stream pollution, and other sanitary engineering problems, and although rules and regulations had been enacted for the protection of certain surface supplies from contamination, no comprehensive investigations had been made to determine the conditions of the water supplies in the State, or to improve them.

Since the establishment of the Division of Sanitary Engineering in 1906, one of the principal, if not the most important, functions of the Division has been the supervision over the sanitary quality of public water supplies. Of about 550 public water supplies in the State all have been investigated and reported on at least once and many of them a number of times.

Rules and regulations for the protection of about ninety surface supplies have also been enacted. Since 1906, the number of persons served by public water supplies in New York State has increased from about 6 000 000 to 8 500 000, and the number of persons supplied with purified or treated water has increased from 700 000 to nearly 7 000 000.

The results of these improvements are clearly reflected in a decrease of the typhoid fever death rate in the State as a whole. Before 1906, the average death rate from typhoid fever for the whole State, including New York City, was 23.4. Since 1906, the average rate has been 9.4, a reduction of 14 per 100 000. It will be noted also that the rate has decreased each year with marked regularity, until 1920 a remarkably low level of 3.5 was reached, a figure which about 20 years ago was generally considered to be the probable irreducible minimum for the United States. In all probability, the rate will be lower, but the decrease necessarily will be less marked in the future than in the past. The figures available up to the end of September, 1921, indicate that the rate for this year will be slightly less than those for 1920.

* Director, Div. of Sanitation, New York State Dept. of Health, Albany, N. Y.

Although other factors, such as improvements in milk supplies, etc., no doubt have had some effect in decreasing the typhoid fever death rate, the speaker believes that the decrease has been due largely to improvements in water supplies.

The municipal authorities of Cohoes, N. Y., constructed filters and commenced sterilizing the water supply in 1911. Between 1900 and 1911, the average death rate from typhoid fever was 85.5, fluctuating from a minimum of about 58 to a maximum of about 133. Since the filters were built, the average death rate has been 17.3 and, for two years, no deaths from typhoid occurred in that city.

Filtration and sterilization plants were constructed in Niagara Falls, N. Y., in 1911. Before that time, the average death rate from typhoid fever was 131.8; since the establishment of filters the average death rate has been 9.4.

Albany had an average typhoid fever death rate of 89.4 per 100 000 before the construction of its filter plant in 1899. Since the filters were built, the average death rate from typhoid fever has been 17.5, and it has been gradually decreasing until in 1920 the rate was about 3 per 100 000.

At Binghamton, N. Y., the average death rate from typhoid before the filters were built, was 56.2, and the average death rate from typhoid since the construction of the filters has been 11.7.

It is evident that in each case a decided drop in the typhoid fever death rate occurred immediately after the construction of the filtration plants. It is also evident that the city, the water supply of which was most grossly polluted before purification, had the highest typhoid rate and the one the water supply of which received the least pollution had the lowest rate. The distance which the pollution has to travel and the velocity of the stream are, of course, important factors in the case of water supplies derived from rivers.

For Niagara Falls, which had the highest death rate of any city in the State before the construction of filters, the water supply is taken from the Niagara River. Buffalo, N. Y., with a population of about 500 000, discharges its untreated sewage into the river about 15 miles above the intake of the Niagara Falls water supply, and the raw sewage from the Cities of Tonawanda and North Tonawanda, N. Y., with a total population of 25 000, is discharged into the river about 10 miles above Niagara Falls. With the sewage of 500 000 people discharging into a comparatively swift stream at a relatively short distance above the water supply intake, it is not surprising that Niagara Falls had a high typhoid fever rate before water purification was provided.

The typhoid death rates at Cohoes and Albany, before the construction of filters were nearly the same, and the raw water is of a somewhat similar character. Cohoes obtains its water from the Mohawk River about 18 miles below where the sewage from Schenectady, with a population of about 90 000, is discharged into the river, formerly without any treatment whatever.

Albany obtains its water supply from the Hudson River about 8 miles below the mouth of the Mohawk River, and the intake is from 4 to 10 miles below Troy, Cohoes, and Watervliet, which have a combined population of

110 000. The sewage from all these cities is discharged directly into the Hudson River without treatment.

The Susquehanna River, from which the City of Binghamton obtains its water supply, receives comparatively little raw sewage within 50 miles of the intake. The typhoid fever death rate at Binghamton, although high, was nevertheless much lower than at either of the other cities referred to.

In closing, the speaker wishes to point out that to Theodore Horton, M. Am. Soc. C. E., who was Chief Engineer of the State Department of Health from 1906 to July 1st, 1921, is due in a large measure the credit for the improvement of public water supplies in New York State.

PURIFICATION OF SOFT COLORED WATERS

By Robert Spurr Weston,* M. Am. Soc. C. E.

Engineers engaged in water supply work are in substantial agreement that a drinking water, to satisfy critical modern consumers, should have an average color of not more than 10 parts per million on the platinum scale, and its maximum color should not exceed 15 parts. Supplies from ground sources and from many lakes and ponds conform to this standard, but most of the clearer surface waters possess a brownish coloration, well above the limit of 15 demanded by the modern consumer. In Massachusetts, according to the reports of the State Department of Health, practically all the ground-water supplies which are free from iron, have colors not exceeding 10, while of 86 surface supplies, 50 or 58% have average colors in excess of this standard. The appearance of these colored waters draws unfavorable comment from Western visitors who are accustomed to water filtered clear and colorless, from turbid streams.

A growing appreciation of the esthetic characteristics of drinking water is leading to the betterment of these colored supplies by purification, the current methods being storage and filtration. Storage for months or years in good reservoirs effects a decolorization of water. In this, iron plays an important part in flocculating minute particles of suspended matter which constitute what is called color. Several examples of this were given by Ralph H. Stearns,† Assoc. M. Am. Soc. C. E., which show reductions of from 4 to 69% through storage. It is most often impracticable to store waters long enough to decolorize them sufficiently to compare them, with a reasonable degree of favor, with filtered waters and the average ground water, and, for this reason, as well as further to safeguard the public health, many stored colored waters are filtered. This practice is usual abroad, and is coming into increasing favor here, as evidenced by the new purification plant at Hartford, Conn., and the plans for the additional supplies for New York City, and Providence, R. I. The first large filters were built at Cleveland, Ohio, and Somerville, N. J., and the second one at Washington, D. C. The filters at Hartford are of the slow type, and although the color of the effluent will probably not average as low as 10 parts per million, a supply of reasonably good appearance is assured by this method. Of course, color removal by slow filters has been the subject of many discussions, and the statements made have rarely taken into account the physical and chemical nature of color.

Most of the color in water is in the form of a colloidal suspension, that is, the particles are so fine and so dispersed in water that they remain in suspension and act like true solutions, except that the Tyndall ray and the ultra-microscope reveal them. These colloidal particles are not all alike. They possess electrical properties, and when electrolyzed some of the particles will migrate to the positive, some to the negative pole. A small part of the color is apparently in true solution and is not affected by the electric current. It is reasonable to believe that colored water from a large lake or reservoir

* Cons. Engr. (Weston and Sampson), Boston, Mass.

† *Journal*, New England Water Works Assoc., Vol. 30, p. 20.

will contain finer particles of color than a river water. This belief is supported by the higher color removal by sand filters supplied by river than by reservoir waters. A slow sand filter will remove one-third of the color, but when treating certain river waters such filters may remove more than one-half the color, although they are usually unable to remove more than one-fifth of the color from a stored water.

There are waters, therefore, which require chemical treatment prior to filtration. In nearly all such cases, sulphate of alumina with or without an alkali has been used. The dosing has been based on the appearance and alkalinity of the water, and the results, especially in small plants operating without laboratory control, leave much to be desired. Recently, George C. Whipple, M. Am. Soc. C. E., has stated:

"The use of alum with short periods of coagulation and mechanical filtration of the ordinary type is, in my opinion, inappropriate to a soft colored Massachusetts surface water. * * * * The corrosion problem in our State is serious and must not be made more so by inappropriate chemical treatment."

The mechanical filter, *per se*, is an efficient device, and the remedy lies in better chemical treatment. If the waters could be treated more scientifically, the period of coagulation might be reduced and the rate of filtration increased. Better treatment, however, must await the application of modern chemical and physical theories to practice, and this will require much investigation and many trials before any rules can be written for the non-technical operator.

At present, sulphate of alumina is added until coagulation takes place, and, in most cases, soda is added to maintain an alkalinity of at least 7 parts per million in the water delivered to the mains. Frequently, this method fails. At some places, such as Warren, R. I., soda cannot be used at certain times of the year, and the alkalinity is maintained by the addition of calcium carbonate in the form of powdered chalk. If sulphate of alumina is added to excess, better decolorization will be obtained, but the treated water will corrode the distribution system. In the one case, the soda has been added to the filtered water. At Wilmington, N. C., the water is first overdosed with alum, and after it has passed through the coagulating basin, it is dosed with enough soda or lime to insure a final alkalinity of 10. In these cases, both the optimum decolorization by sulphate of alumina and the inhibition of corrosive action is attained. At Exeter, N. H., it was impossible, even by adding sulphate of alumina to excess, to reduce the average color much below 20 parts per million. Apparently, the water contained a large quantity of positively charged coloring matter which was not affected by aluminum hydrate having the same charge. By pre-treating the water with 0.5 parts of chlorine per million, a condition was brought about under which treatment with a small dose of sulphate of alumina easily reduces the color below 10 parts per million.

Ordinarily, one believes that if an equivalent quantity of soda is added to a unit dose of sulphate of alumina, aluminum hydrate will be produced. Try this in some cases in practice, and what results—a re-solution of the color.

In some cases, reduce the equivalent dose of soda to, say, one-half, and a good decolorization may result. These facts are known, but the principles on which they are based are not yet clear.

There is also the problem of after-precipitation. In at least four rapid filter plants supplying New England towns, some of the aluminum hydrate passes the filters in a colloidal form to coagulate later in the distribution system. This was the chief of the many objections which the late Hiram F. Mills, Hon. M. Am. Soc. C. E., raised against alum treatment. This fault is noticed even at plants with coagulating basins of relatively large capacities, although not so frequently as at plants where the chemicals are applied directly to the influents of pressure filters. The trouble occurs most frequently in cold weather when all chemical reactions are retarded.

From what has been said, it is obvious that water purification experts are trying to solve what is, perhaps, the most difficult water purification problem, without a knowledge of the factors which enter into it, and until they can elucidate these factors, the demonstration of the theories is impossible.

For guides, engineers have depended largely on the color and alkalinity determinations. What do these mean? Simply a measure of the intensity of the one and the combining power of the other. No regular determinations record the nature of the color, and although the brown of one water may appear to be similar to the brown of another, it is no sign that they will respond to the same treatment. Thorndike Saville, Assoc. M. Am. Soc. C. E.,* showed how varied were the components of color in water. His experiments demonstrated the ultra-microscopic character of the "suspensoids" and "emulsoids", to use the modern terms, which make up the bulk of color in water, and that these carry electrostatic charges, positive or negative, depending on, and varying with, the water. Usually, the color particles have a negative charge.

It is obvious that the difficulty of finding the charge of the color particles and the necessary treatment is not much facilitated by the ordinary water analysis. In practice, it is assumed that the color carries a negative charge, and aluminum hydrate, with its positive charge, is used to neutralize and coagulate it. This treatment does not dispose of the positively charged color particles, except that these may be removed by the absorptive action of the precipitate produced by the negatively charged particles and the hydrate. Special treatment for these positively charged particles is necessary, and the substances added must not neutralize the effect of the positive aluminum hydrate. The good effect of chlorine at Exeter, and of carbon dioxide in the experiment of Mr. M. C. Whipple† in increasing the electro-negative character of the color and, consequently, the decolorizing power of a given dose of sulphate of alumina, leads one to hope that methods for determining the electrostatic charges of color particles will come into more common use and their results will indicate more rational treatment than that commonly used at the present time.

* *Journal*, New England Water Works Assoc., Vol. 31, p. 78, *et seq.*
† *Loc. cit.*, p. 116.

The alkalinity determination simply expresses the quantity of sulphuric acid in terms of calcium carbonate required to neutralize the water. It does little else. Practically all the colored waters supplied to towns are alkaline. Yet, how different are the treatments required by waters of about the same alkalinity and color. An equivalent of magnesium hydrate has the same combining power as an equivalent of caustic soda. The former is called a weak, the latter a strong, alkali, and these adjectives describe their effects. By determining the hydrogen-ion concentration, these differences of potency can be measured. This determination is coming into use; it has already been made part of the daily routine at Baltimore, Md., and other places. Apparently, there is an optimum hydrogen-ion concentration for each water, where coagulation is most nearly complete. It is not far from PH = 7.0. The hydrogen-ion determination is not difficult, and the speaker believes that it may show what conditions of the dissolved salts in water, that is, the electrolytes, are most favorable for flocculation of the colloidal color, probably in many cases by suggesting treatment with other chemicals as well as with sulphate of alumina.

The problem, therefore, is to substitute a specific for a panacea treatment by a more accurate analysis of color and a more proper dosage with chemicals, also by the creation of the most favorable condition in the solution—the water—for the flocculation and precipitation of the neutralized colloidal color. This seems to be complicated, but the speaker believes it will be worked out to a satisfactory solution in practice. Indeed, the collection and study of the more refined electro-chemical data should explain the successes and failures in practice, and should help to rationalize the treatment of colored waters. On the practical side is the lure of a greatly reduced cost for chemicals, which should stimulate research in this important field.

THE OPERATION OF RESERVOIRS FOR WATER SUPPLY

By Samuel A. Greeley,* M. Am. Soc. C. E.

The developments of storage for water supply throughout many parts of the Upper Mississippi Valley is frequently a relatively costly project. The river valleys are wide and flat, and the slope of the streams is moderate. Thus, at Decatur, Ill., to impound about 9 000 000 000 gal. to furnish an estimated minimum yield of 42 000 000 gal. per day, it is necessary to flood about 5.5 sq. miles and the total cost of the project is almost $2 000 000. Several other water-impounding projects which have come to the speaker's attention, have called for expenditures in excess of bond limitations and have been financed by popular subscription.

Furthermore, south of Wisconsin and Minnesota, ponds, lakes, and streams for recreation purposes are scarce and inaccessible and by no means as plentiful as they are throughout New England, for instance, and parts of New York State and New Jersey. For these reasons, among others, there is a strong disposition to permit the use of these reservoirs for recreation purposes, including bathing, boating, fishing, and the like. The most extreme case which has come to the speaker's attention is Lake Milton, in Ohio, which furnishes the water supply for Youngstown, Warren, Niles, and other small communities in Ohio. This reservoir covers about 2.65 sq. miles and impounds about 9 000 000 000 gal. There are a number of resorts about its shores, and bathing, boating, fishing, and picnicing are allowed. Below the dam, the water flows several miles in open channel to the intake of the filter plant, receiving pollution on the way, which masks the effect of reservoir use.

It should be noted especially, however, that many of the surface water supplies of the Upper Mississippi Valley are turbid and otherwise unsatisfactory without filtration, so that modern water filtration plants are, in general, in operation in the case of the larger projects. This circumstance tends to render officials and the public less sensitive to the possibilities of pollution at the source.

Earlier Discussions.—The use and maintenance of reservoirs has been under consideration from time to time since 1907, when a thorough discussion† was presented before the Society on the relative value of the control of drainage areas and the installation of water filtration plants for the protection of public water supplies. The discussion at that time, however, did not relate primarily to the use of reservoirs as this use affected a safe load on water filtration plants.

A later, and a very able, discussion was presented in 1920, by X. H. Goodnough, M. Am. Soc. C. E., before the New England Water Works Association, deprecating the use of reservoirs for fishing and boating and instancing a number of cases where permission to fish resulted adversely. In most of these cases, however, the relation of water filtration was not stated.

In a still further discussion,‡ the following conclusions were offered by George A. Johnson, M. Am. Soc. C. E.:

* Hydr. and San. Engr., Chicago, Ill.

† *Transactions*, Am. Soc. C. E., Vol. LIX (1907), p. 367.

‡ *Journal*, Am. Water Works Assoc., July, 1921.

(*a*).—Maintain the catchment area in as sanitary a condition as practicable; that is, guard against gross pollution entering the streams and lakes which drain the water-shed.

(*b*).—Store the water in natural lakes or artificial reservoirs, provided such storage is available or dictated by sound engineering principles.

(*c*).—Coagulate and filter.

(*d*).—Sterilize.

These comments, however, are not specific as to the use and protection of reservoir supplies.

Apparently, this matter is not finally settled in all cases, as indicated by a recent Act submitted to the Massachusetts Legislature relative to the use of Lake Cochituate in the Town of Natick for boating and fishing. The officers of the New England Water Works Association have protested against the passage of this bill.* Efforts should be directed to (1) the control of human activities to prevent undue pollution; and (2) the control of natural processes to prevent deterioration of physical qualities.

Principal Considerations.—The operation of reservoirs for water supply may be discussed from two principal considerations: (*a*) the use of reservoirs for other than water supply purposes; and (*b*) their maintenance for water supply purposes.

The first consideration includes the regulation of the reservoir for bathing, boating, fishing, picnicing, and the development of the shores into camps, resorts, and residential and industrial districts. The effect of these various uses on the condition of the water as affecting the safe load on water filtration plants is the present-day criterion.

The second consideration includes the necessary operations for the maintenance of the reservoir, such as the control of objectionable growth of microscopic organisms, the proper draining and clearing of the banks, the protection of the shores, the regulation of storage, the handling of silt, the control of fish life, the drainage of swamps, the control of erosion, and the like.

In connection with the approaching completion of the impounding reservoir at Decatur, Ill., the speaker has gathered some data indicating practice along these general lines in a number of other situations. (See Tables 5 and 6.)

Summary of Data on the Use of Impounding Reservoirs.—Table 5 shows the practice with filtered water supplies. In general, it is indicated that no bathing is allowed, with the exception of Youngstown, Ohio, and at Fort Worth, Tex., some bathing is permitted. There is indicated a more general permission for boating, as this is forbidden entirely in only seven towns out of the fourteen records available. Fishing from the shores is almost generally permitted, and quite generally also from boats, although this latter practice is commonly regulated through permits or licenses. Picnicing and camping seems also to be allowed, with the establishment of camps and resorts permitted in about one-half the cases. Some method of patrol is almost always undertaken, and among the more comprehensive of these methods are daily inspections by five mounted patrolmen over a drainage area of 110 sq. miles for the Oakland, Cal., water supply.

* *Journal*, New England Water Works Assoc., September, 1921.

Table 6 indicates the data for unfiltered water supplies. In only one case is bathing reported as permissible, that is, at Paris, Ill., in which city the water is not used for drinking. Boating also is forbidden, whereas fishing from the shores is forbidden in seven cases out of eleven. Fishing from boats is also generally forbidden, and this is also true of picnicing, camping, and the development of resorts.

In the case of the impounded or lake supplies for Boston, Mass., and New York City, very careful control is exercised, fishing and some boating is allowed by permit, and some bathing occurs near some of the New York reservoirs.

Practice thus indicates a somewhat freer use of reservoir waters in the case of filtered supplies.

Comments on Bathing.—The matter of bathing appears to be the most important consideration. It should be considered not only for its effect on the quality of the water in the reservoir, but also for its effect on the bathers themselves. The effect of crowded bathing beaches on the bathers has recently called for the serious attention of the Health Departments in Chicago, Ill., Milwaukee, Wis., and elsewhere along the Great Lakes. A suggestion is offered that better bathing facilities can be provided in specially designed pools or ponds, in which the circulation and purification of the water can be controlled. With present-day understanding of the quite general distribution of typhoid carriers, the regulation of bathing assumes increasing importance. For a short time in 1921, several public bathing beaches in Chicago were closed.

Maintenance of Reservoirs.—No large impounding reservoir for water supply can be left to itself, and some more or less continuous maintenance is required. In the first place, developments on the drainage area above the reservoir should be convassed frequently so that gross pollution may be avoided. In the second place, the development of undesirable microscopic growths must be watched and controlled. Methods of control include a reasonable removal of the causes of such growths, the destruction of such growths by the application of minute quantities of copper sulphate, and the improvement of the water by aeration before filtration.

The third consideration involves the maintenance of satisfactory shore conditions, which can often be accomplished by draining, clearing, and burning over marginal areas during low water. It is believed to be particularly important that constant patroling should be undertaken, probably by boat and automobile, so that the establishment of gross nuisances may be prevented at all times, as well as minor infringements of the reservoir use.

Recent English Data.—The speaker's attention has been called to a moderate use of impounding reservoirs for fishing in England. A book by Ernest Phillips, entitled "Trout in Lakes and Reservoirs", has been published, which offers some interesting data. It appears that within the last few years about forty or more English cities have stocked their city water supply reservoirs with fish and opened them to the public. In some of these cities, fishing tickets are issued, which cost at Manchester 25 cents per day and at Huddersfield 50 cents per fishing day. The speaker is not informed as to the extent of water filtration at these supplies, nor as to which, if any, are

chlorinated. It is the general understanding in the United States that few of them are filtered. An interesting account of these supplies appears in the *Outlook* for October 12th, 1921.

Rules and Regulations.—A number of rules and regulations governing the use of reservoirs have been published and others have been suggested. Among the most complete are those of the Massachusetts State Board of Health, the Department of Water Supply, Gas and Electricity of New York City, a suggested law by W. H. Dittoe, M. Am. Soc. C. E., Chief Engineer of the Ohio State Board of Health, and ordinances recently passed at Dallas, Tex., and elsewhere. The aim of these rules and regulations is to prevent entirely the use of the reservoir for fishing, bathing, boating, and the like, or to permit some boating and fishing under careful regulation through permits and licenses. Bathing appears to be quite generally denied.

Summary and Conclusions.—The brief time available for the presentation of this subject of the operation of reservoirs for water supplies, and the multitude of differing local conditions, do not permit general definite conclusions. Practice and experience indicate that bathing, except under most favorable conditions, should not be permitted, and that consideration should be given to the protection of bathers as well as to the protection of the water supply. With unfiltered supplies, the tendency is frequently against boating, fishing, and the like. In the case of filtered supplies, the use of reservoirs for such purposes appears to be increasing under the most thorough and careful sanitary patrol.

DISCUSSION

LOUIS L. TRIBUS,* M. AM. SOC. C. E.—For a great many years the speaker's firm had under its observation and care a Western water-works system, the supply for which came from a flashy river, varying greatly in alkalinity and turbidity.

During different seasons and storm conditions, the alkalinity ranges from 40 to 320 parts per million and the turbidity, from zero to 5 000 (5 000 marks the limit on the gauge); how much worse it has been is not known. The point of interest, however, was the treatment of the water with coagulant. Taking the average through the year, 1½ to 2½ grains of sulphate of alumina were required per gallon, and, at times, it was necessary to increase the dose greatly. On one occasion, when the turbidity was at the maximum, the water would not yield until the alum dose was increased to 20 grains. Then, it suddenly yielded and although the conditions seemed to be the same, the alum dose was decreased at once to 11 and then to 7 grains, with perfect results.

Another fact of special interest is that an advantage was gained by dosing the raw water at different stages in its passage. From the river, the water first passed through four successive sections of a sedimentation or coagulation basin; and then to mechanical gravity open filters. Alum was first added at the point where the centrifugal pump took the water for discharge into the first basin, and since the water entered near the bottom of that first basin, a second dose could be given. The flow passed through a port about 3 ft. from the bottom of the wall, between the first and second chamber, and, from the second to the third section, it passed at a little higher elevation. At this port a third dose of alum was added. The water then passed through the third basin into the fourth, and through that and a short pipe line to the filters. The final dose of alum was given just before the water reached the filters. It was found that by using these successive proportional charges, far better results could be obtained than by using the full dose at any one point. The clearest water was neither near the bottom nor at the top, but from about 6 in. to 1 ft. below the top.

G. F. CATLETT,† ASSOC. M. AM. SOC. C. E.—The discussion on colored waters by Mr. Weston is interesting, particularly his reference to such waters in Eastern North Carolina. Considerable study has been, and is being, given to the treatment of these waters as they occur in that State and some interesting results have been published regarding the treatment of the colored water at Wilmington, N. C.

The outstanding facts brought out in connection with these studies, are that the treatment of colored water requires close and scientific regulation of chemicals and of the general treatment, and that it does not require as long a retention time in the coagulating basins and probably not as low a velocity as is required by turbid waters.

* Cons. Engr. (Tribus and Massa), New York City.

† Prin. Asst. Engr., North Carolina State Board of Health, Raleigh, N. C.

In the case of the colored waters of North Carolina, and it is true in general of those found elsewhere, the alkalinity is rather low, and additional alkali must be applied. In applying this alkali a careful adjustment of the ratio of aluminum sulphate to alkali was found to be necessary, so that the hydrogen-ion concentration will be close to the iso-electric point. If this is done, coagulation will occur much more quickly than in the case of turbid, clay waters, and the floc will be in larger, heavier particles. If slightly more alkali is added than is needed to secure the iso-electric point, coagulation will occur in such small particles that no satisfactory sedimentation or filter efficiency can occur. It is obvious that this required control must be under complete laboratory test and under the supervision of an operator thoroughly conversant with the principles involved. In order to secure a factor of safety against free alum going over to the filters, it is found necessary to add a small quantity of alkali as a secondary treatment after coagulation and sedimentation. The quicker coagulation secured under proper treatment and the larger and heavier floc are the reasons for suggesting a lower basin retention time and a higher permissible velocity in the basin.

In treating the colored water at Wilmington, where complete laboratory tests and scientific control is provided, satisfactory color removal is secured with the economical use of chemicals. At Elizabeth City and Lumberton, where there is no trained technical supervision, rather unsatisfactory results are secured, with a much higher consumption of chemicals.

The reference to the brackish water at Wilmington is entirely aside from the difficulty encountered in treating a colored water. Following an abnormal dry spell, such as has been experienced this year (1921), in conjunction with certain wind and other conditions in the ocean, sea water is backed up thirty miles distant to the intake. The October, 1921, report from the Wilmington plant shows chloride content as high as 1 600 parts per million. The same trouble is experienced to a greater or less extent at other towns along the coast. As the condition exists for a short period only, the remedy is raw-water storage sufficient to carry over the duration of salt water.

It is of interest that this condition at Wilmington, in its more aggravated form, was coincident with the construction of locks and dam on the river above the intake.

JOHN R. BAYLIS,* ASSOC. M. AM. SOC. C. E.—Hydrogen ions having been mentioned by Messrs. Whipple, Hazen, and Weston, the speaker will discuss that subject briefly. The laboratory at the Montebello Filters, of the Baltimore City Water Department, was one of the first to use hydrogen ion in plant control and it is now one of the most important tests. The water at Baltimore is comparatively soft, the alkalinity being about 40 and the total hardness about 50. It is corrosive before treatment, and after the application of alum, unless neutralized by an alkali, it is so corrosive that when it reaches the consumer it may look about as turbid as it did before filtration, due to corrosion of the pipes. It is necessary, therefore, to reduce its cor-

* Prin. San. Chemist, Baltimore City Water Dept., Montebello Filters, Baltimore, Md.

rosive qualities, which is now done by adding lime near the outlet of the mixing basin.

Mixing basins are a feature frequently overlooked in filter design, and it may be well to discuss briefly this part of the plant which helps bring about the chemical reactions. Some years ago, the speaker had the experience of trying to operate a plant which had no mixing basin, and after one year of unsatisfactory efforts, a basin was constructed, and immediately the desired results were obtained. Some interesting experiments have been made in California on mechanical agitation to produce the desired mixing, and the speaker believes there is something in that method, because in Baltimore, several years ago, when iron and lime were used as a coagulant, good coagulation was frequently hard to obtain. It required about ½ hour for the water to pass through the mixing basin, which is longer than in most plants. Experiments showed that when this water, which had received the ½-hour mix without producing a satisfactory coagulation, was stirred slowly for 20 or 25 min., excellent results were produced. In recent experiments on mechanical agitation, the speaker has found the time element important, as well as the saving in chemicals. A turbidity requiring about ⅔ grain per gal. of alum and ½ hour in the mixing basin of the plant, could be properly coagulated with ⅔ or ½ grains per gallon, if stirred for 25 or 30 min. with the experimental apparatus.

It has been stated that coagulation with colored waters is difficult, but the precipitation is very rapid when once obtained. The chances are that this colored water was overdosed with chemicals, which produces rapid precipitation after the floc is formed. A longer period of mixing may change the results with considerable saving in chemicals. The speaker favors large coagulating basins even though there may be rapid precipitation. If the total capacity is not needed, longer periods between cleaning may be allowed. From experiences in Baltimore, larger basins are preferred. Chemical reactions are sometimes slow, and, at times, it seems that such reactions are not complete until after the water has passed the filters. The capacity of the basins, however, does not always give an indication of the time in passing through, as float tests have shown that, in less than 1 hour, part of the water may pass through basins having capacities of 2½ or 3 hours.

It is possible to prevent corrosion almost entirely by adjusting chemical treatment to the proper hydrogen-ion concentration. With soft waters this may mean a PH value of nearly 9.0 and with hard waters the value may be as low as 7.0, or even less, without producing corrosion. For most waters, in adjusting the hydrogen-ion concentration when alum is used, the alkali should be added after filtration. Preparations are now being made at Baltimore to add the lime after filtration. The water before treatment has a PH value of about 7.0, which is reduced to about 6.5, or less, by the addition of alum, and it is later adjusted to about 8.4 or 8.6 by the addition of lime. There seems to be nearly complete precipitation of the alum if the PH value is not below 6.5, but beyond that it may not be complete. On account of the low alkalinity in some waters, it may be necessary to add some of the alkali before the alum, but only enough should be added to produce a PH value of about 6.5 after application of the alum, and then adjust it to the proper

hydrogen-ion concentration after filtration. In Baltimore, it is possible to re-dissolve about one-half the aluminum hydrate by applying lime in doses slightly higher than are necessary to the coagulated water. These re-dissolved compounds may have no effect on the water, but chemicals are wasted by this practice.

The hydrogen-ion concentration is one of the easiest determinations to make, and possibly is the only test that will enable the filter operator to be sure of the corrosive qualities of the water treated. As soon as the proper concentration is determined for a certain water, the necessary adjustments can be made, and complaints about corrosion or red water will cease. The speaker believes that the hydrogen-ion determination is one of the most important tests.

P. H. Norcross,* M. Am. Soc. C. E.—In the broad field of mechanical filtration, several types of filters which might have been referred to, have not been mentioned by Mr. Whipple in his discussion, namely, the drifting sand filters which are operated at Toronto, Ont., Canada, and filters of the pressure type, which are used in Atlanta, Ga. The filters at Toronto are operated successfully at a capacity about 40% higher than the usual gravity type. In Atlanta, there is located the largest filter plant of the pressure type in the United States. It has a rated capacity of 3 000 000 gal. of the old Hyatt type and of 18 000 000 gal. daily of the Continental Jewel pressure type. These filters are operated as gravity filters under about 30 ft. of head, and during the season of peak demand, have operated successfully at 100% overload. This discussion is not a brief in favor of this type of filter plant, but indicates its flexibility. The City of Atlanta is doubling its filter capacity, the program contemplating 21 000 000 gal. daily of the open gravity filter type.

In speaking of filtration Mr. Hazen referred to the character of water to be treated. On the eastern seaboard of the Appalachian and Blue Ridge Mountains, there are two main classes of water to be considered. The larger of the two classes are surface streams which carry heavy turbid red clays, and are located principally above the coastal plain. Below the coastal plain and adjacent to tide-waters, the usual plan of securing a municipal water supply is from deep wells. Pensacola and Jacksonville, Fla., Savannah, Ga., and others are using water of this character successfully.

Little trouble is experienced in the proper coagulation of water in the Appalachian and Blue Ridge sections, for during the greater part of the time there is sufficient alkalinity. The main difficulty is during certain seasons when there is a lack of alkalinity which must be provided artificially. In his comments, Mr. Weston has mentioned Wilmington, N. C. A rather interesting sidelight on the water supply of Wilmington developed during the summer of 1921. This city draws its water supply from the east fork of the Cape Fear River, the flow of which is much less than that of the western branch, the confluence of the two occurring at Wilmington. During the recent drought, the tidal water backed up beyond the intake of the city plant to such an extent that the supply contained approximately 1 200 parts per million of sodium chloride.

* Cons. Engr., Atlanta, Ga.

The speaker was impressed by the comments of Mr. Holmquist regarding the decrease of typhoid rates. However, in commenting on water supplies of different municipalities, results should be compared with reference to the type of water treated. A comparison of typhoid rates between cities of the same size, in different parts of the United States, is not complete without all the information as to the type and character of water used.

H. MALCOLM PIRNIE,* ASSOC. M. AM. SOC. C. E.—It has been said that coagulation basins which have a storage period of a few minutes, are adequate and preferable. It has also been said that the iso-electric point, as indicated by a P H value of 7, is the required hydrogen-ion concentration necessary for the best coagulation. These statements evidently come from experience with waters which coagulate rapidly and best at a hydrogen-ion concentration of P H = 7. Experience with other waters, however, has proven that long periods of coagulation and different P H values are sometimes required for good coagulation.

For many years, coagulation has been conducted with an acceptable degree of success, with the aid of standard methods of determining alkalinity and color by titration with methyl orange and comparison with color standards. Now, the new hydrogen-ion test has been developed. It is a new test and will give much interesting information, but it will not give at once a standard hydrogen-ion concentration to which all waters may be adjusted to obtain the best coagulation.

There are waters in which the nature of solids, particularly organic colloids, varies from hour to hour and from season to season, notably in waters which are polluted with industrial wastes and sewage. These waters do not contain a constant percentage of given organic matter, and the colloids may vary in their electrical properties and degree of adsorption for the added coagulant. In these circumstances, it is essential, with present understanding of chemical treatment, to have a balance wheel in the process, to equalize the effect of variations in the nature of these colloids, and large basins are useful in this connection. One particular plant, where there is a storage of 8 days for the coagulation period, is producing an effluent much better than it was possible to obtain in former years with a storage period for coagulation of 4 hours; in fact, it is now possible to take the water from the river with a color which is sometimes about 150, dose it, let it pass through this basin, and after passing the basin, give it a secondary dose of a small quantity of alum, and obtain a color of zero, after filtration. It is interesting to note that at the start, before any alum is added, this water has a P H value of less than 7. Before a floc can be obtained, it is necessary to reduce that P H value to between 5 and 6, which is considerably below the so-called iso-electric neutrality point of P H = 7. It is evident, therefore, that there is not a definite P H value for all waters, which may be used to determine the required alum dose. The required P H value will vary, depending on the kind and condition of colloids present in the water.

* Cons. Engr. (Hazen, Whipple and Fuller), New York City.

Colloid chemistry has suggested certain ideas which can be applied to water treatment. The physical action of colloids may be used to remove them without the aid of chemicals. This has been demonstrated recently in treating a well water containing a considerable quantity of iron in the ferrous state, which is converted into the ferric state by aeration, and simply passed upward through a definite bed depth of gravel. The ferric iron colloids which are so small that they will pass through filter paper and will not be removed in appreciable quantities by storage for many hours, are absorbed on the surfaces of the gravel stones. The bed is graded from 4-in. gravel at the bottom to ½-in. gravel on the surface, and the depth of the bed is 9 ft. An iron reduction from 7 parts per million down to a trace, with an almost complete removal of colloids, is effected. The adsorption of the precipitated iron by the wetted gravel surfaces and the greater adsorption of the iron colloids on the surfaces of the precipitated iron, are responsible for this almost complete removal of iron from the water. Physical forces play the major part in the purification.

It must be borne in mind that each new idea simply provides another tool with which to work, and that it is not a solution of the problems which engineers have in hand. The determination of the P H value may help to fix the nature of the colloids in a particular water, which would be a step toward working out for that water a definite method of treatment, but a method applicable to one water will not apply to all waters, or even to water at different locations in the same stream with intervening pollution from sewage or industrial wastes.

C. M. Baker,* Esq.—Mr. Emerson's discussion regarding the effect of gas-plant wastes on the taste and odor of chlorinated waters is interesting, especially since this condition has been a live question in the City of Milwaukee for some time. In the fall of 1918, before the speaker took up the work with the State Board of Health, exceedingly objectionable tastes and odors prevailed in the water supplied to the citizens of Milwaukee. In fact, it has been authentically stated that these conditions were so severe as to make the use of foods cooked in the water objectionable. The taste was ordinarily described as a medical taste, and did not resemble the taste of waters treated with an excess of chlorine. Furthermore, the tastes and odors occurred at infrequent intervals, not continuously, and the quantity of chlorine applied appeared to have little, if any, effect on the production of the objectionable conditions.

An extensive investigation was conducted, largely by the chemists of the Water Department and the City Health Department, which consisted in the collection of samples of water from the rivers and harbors in Milwaukee, and also of different industrial wastes. These samples were treated with an excess of chlorine, which later was driven off by boiling, and the test was made by tasting or smelling the samples thus treated. It was determined in this way that the taste-producing properties were confined exclusively to those wastes from industries producing coal-tar derivatives; other wastes seemed to have no effect. It was further determined that phenol was the most objectionable substance in producing these conditions. The investigators claimed that by

* State San. Engr., State Board of Health, Madison, Wis.

their method of testing, previously mentioned, the presence of phenol in a solution, as great as 1 part in 500 000 000, could be detected. At that time (1918), the State Board of Health and the Governor of Wisconsin were consulted. Numerous hearings were held, and, finally, by testing samples collected from Lake Michigan, the source of the trouble was traced directly to a Government phenol plant at Carrollville, about 15 miles from the Milwaukee intake. The matter was taken up with the Government and, in the fall of 1918, this plant was closed.

It was thought that the closing of the Carrollville plant had eliminated the objectionable conditions; but a slight recurrence of the odor was noticed in December, 1919, and again in March or April, 1920. This latter condition was more severe than that of December, and the State Board of Health was again called in consultation. At that time, the plant at Carrollville was operating on an entirely different basis, and was discharging no phenol wastes into the Lake. It was apparent, therefore, that the source of the pollution was elsewhere. The previous investigation, however, had failed to show the taste-producing quality in any of the samples collected in the harbor or the rivers. It was apparent, therefore, that the evidence was not conclusive against the two or three plants in Milwaukee known to produce wastes which were apt to cause the objectionable conditions. A complete investigation, therefore, was outlined and undertaken; thousands of samples were collected from the rivers and harbor, and tested.

Three rivers enter the harbor at Milwaukee, namely, the Milwaukee from the north, the Menomonie from the east, and the Kinnickinnic from the south. The Milwaukee Coke and Gas Company discharges its wastes into a slip tributary to the Kinnickinnic River and the Milwaukee Gas Light Company directly into the Menomonie River. The Milwaukee River and the Kinnickinnic River are flushed by tunnels from the lakes; the Menomonie River, however, is not flushed.

In the testing of samples, it was soon learned that there was only occasionally taste-producing qualities in the samples collected from the harbor outlet. By continuing the tests up the stream, the Milwaukee River was eliminated as a factor, but rather intense concentration was found in the Menomonie River—coming from the east—particularly just below the Milwaukee Gas Light Plant. On one or two occasions the taste-producing quality was observed in the water at the mouth of the Kinnickinnic River, and, on a few occasions, in the harbor outlet. A careful study of the relation of wind conditions with reference to the taste in the water supply indicated quite conclusively that the conditions necessary to cause tastes were a west wind, followed almost immediately by a southwest wind. Certain intensity and duration of the wind was also necessary. Furthermore, it was learned that samples collected from the harbor outlet showed taste on test only during westerly winds. It was concluded, therefore, that the conditions causing taste and odor in the Milwaukee water supply were: First, the accumulation of wastes from the Milwaukee Gas Light Company in the Menomonie River and from the Milwaukee Coke and Gas Company in the slip tributary to the Kinnickinnic River; and, second, by west winds carrying the accumu-

lated pollution out of the harbor, followed by southwestern winds carrying the pollution to the water intake.

The solution suggested was to provide for the continuous discharge of the wastes, thus prohibiting the intermittent discharges caused by changing winds. The wastes from the Milwaukee Gas Light plant, therefore, were pumped into a sewer discharging directly into the Milwaukee River, which sewer is flushed daily. The slip which receives the waste from the Milwaukee Coke and Gas Company was dammed and a pipe carried back of the dam for a distance of about 40 ft., to provide for the gradual discharge of the waste from this slip. Since these changes were made, there has been no recurrence of the objectionable conditions.

The situation in Milwaukee has been extremely serious. It has been so serious and such publicity has been given to the city's experience that much difficulty has been encountered in securing the installation of chlorine plants for the treatment of public water supplies in the State of Wisconsin. Some citizens of Milwaukee wished the chlorine discontinued although the necessity of this treatment was clearly demonstrated by an occurrence in 1916. One night, an employee of the Water Department shut off the chlorine without the knowledge of the Superintendent of Water-Works, or of the Health Department, and the apparatus was shut down for about 8 hours. There followed, during the next few days, between 50 000 and 60 000 cases of gastro-intestinal trouble, and within the next few weeks between 400 and 500 cases of typhoid fever, with between 40 and 50 deaths—very conclusive evidence of what chlorine is doing for the water supply of Milwaukee.

One more point regarding the effect which this condition may have over the United States. In the fall of 1919, the State Board of Health started a movement in Sheboygan to secure chlorination of its public water supply. The sewage from the city is discharged into Lake Michigan without treatment, and the water of the city is taken from the Lake untreated. The typhoid death rate for Sheboygan was about five times that of the State as a whole, and about three times that of Milwaukee. Serious opposition developed in the city, however, to the installation of chlorination, and it was only after the Department of Health issued a definite order and enforced it that such installation was secured.

GEORGE W. SIMONS,* JR., ESQ.—The discussion of Professor Winslow, treating of the reduction in the typhoid fever death rate, has been interesting to the speaker, but one or two points mentioned by him should be further amplified, especially by one familiar with health problems in the Southern States.

Health workers in the Southern States, and particularly those in the Southeastern States, are not so greatly concerned with the problems of water-borne typhoid infection as they are with infection from other sources. These States may be roughly classed as rural in comparison with the thickly settled Northeastern States the total area of which in some cases is far less than the area of many smaller counties of the Southern States. In a greater part of the

*Chf. San. Engr., State Board of Health, Jacksonville, Fla.

southern regions, municipal water supplies are taken principally from deep ground sources and, therefore, the chance of water-borne typhoid infection is considerably lessened. In all Southern States where soil-pollution activities have been conducted, the reduction of typhoid death rates has been clearly reflected in those areas. Therefore, at this time, the typhoid problem of the Southern States is largely one of rural sanitation. As these States become more thickly settled, however, and ground-water supplies become depleted or depreciated in quality and are replaced by surface waters, typhoid will become more of a water problem.

Professor Winslow has reproduced some interesting figures showing reductions in typhoid mortality rates in the registration area as they were originally, and, also, as they are now constituted. His remarks inferred that the recent admittance to the registration area of States having a lower sanitary standard was reflected by the lessening typhoid reduction in the present area, as compared with that of the original States. Unquestionably, the admittance of many Southern States into the registration area has had an effect on the rates, but, even so, one point deserves attention. Since 1910, fourteen States have been admitted to the registration area for deaths; of these, eight are Southern States, in which health activities are receiving more attention than ever before.

An examination of the typhoid mortality rates as issued by the Bureau of Census indicates that, during the period from 1900 to 1910, the typhoid death rate declined 13.3 points, and, from 1911 to 1919, 10.5 points. During the latter period, eight Southern States were admitted to the registration area.

Health work in the South is becoming more and more active, a fact which can be verified by an examination of the results accomplished. As stated previously, the typhoid problem in the South is largely one of rural sanitation, yet great strides are being made in the combat of this infection.

In Florida, for instance, the typhoid mortality rate was 27.8 in 1918; 18.4 in 1919; and 14.3 in 1920, which indicates a steady decline. The rate for 1921 will show an increase which has been a source of some apprehension to those studying it, but since the speaker has discussed the problem with workers from other States, the seriousness somewhat diminishes, because many States will experience a high typhoid rate this year; in fact, a representative of one of the largest Northern States has stated that he felt the typhoid mortality in his State would almost return to the 1913 figure.

There is still a final point which should be referred to, namely, the fact that much of the typhoid in a tourist State, such as Florida, is imported from elsewhere; in other words, Florida is charged with an undue typhoid mortality. During 1920, seven typhoid deaths were non-residents.

M. N. Baker,* Esq.—A few years ago, in discussing the diminishing typhoid rate, the speaker cast about for a figure which if attained might entitle a city or State to be placed on a typhoid honor roll. The figure decided on was 5 for a city and 7½ for a whole State. The rate has fallen so much since then that, in its summary of typhoid fever deaths in 1920, in cities of the United

* Assoc. Editor, *Engineering News-Record*, New York City.

States having more than 100 000 population, the *Journal* of the American Medical Association of March 26th, 1921, sets the typhoid honor roll mark at 2 deaths or less, per 100 000 population. With that low rate (taking into account a correction in a later issue) 11 cities appear on the roll, while 30 cities had typhoid death rates of 5 or less per 100 000. That is in striking contrast with the rate of 20 per 100 000 mentioned by Professor Whipple as that generally used some years ago in discussing the extent to which typhoid should be reduced in order to clear a city of the charge that the disease was due to the water supply. As the typhoid rate approaches 1 per 100 000 population, cities of less than that size have a zero rate now and then or, perhaps, for several years in succession. The latter has been true of Montclair, N. J., a city of about 30 000 population, where there has not been a death from typhoid for the past four or five years. Notwithstanding this absence of typhoid in Montclair, there has been much local agitation over the character of the water supply, although it is filtered and chlorinated. This shows what may be expected in many communities: Low typhoid or none at all, and yet more popular agitation over the water supply than when the typhoid rate was 20, 50, or even more.

With typhoid so largely reduced, there seems to be a chance of uncovering or exposing other areas of trouble—some of the more or less mysterious intestinal disturbances. Whether these are due to public water supplies is an interesting and important question which needs extensive and intensive investigation. The time seems to have passed when, in a progressive city which is utilizing the engineering and other technical knowledge now available, there need be great concern over typhoid, as far as water supplies go, provided only that the cities live up to the knowledge which is extant, both in the design and construction of water-works and in their operation and general practices as well.

Since this agitation in regard to water supplies in communities where typhoid has virtually vanished, comes very largely from the medical profession, or is backed by it, there seems to be occasion for urging on the medical men, if they are going to pursue that course and ask the communities to expend large sums of money for further water treatment, to make a careful study of their patients who have intestinal troubles, and try to find out some things which at present they do not know regarding these disturbances. In some communities, now and then, these intestinal troubles affect hundreds or thousands of people in a short time, but produce no typhoid. That was the case in Montclair in 1918 and, later, in Cambridge, Mass., which had a typhoid rate of 1.7 in 1919 and 2.7 in 1920. There is still plenty for engineers to study, but members of the medical profession should go further in their studies than they have yet done, if they are to ask engineers and the public to increase the already large expenditures to improve the quality of water supplies.

H. N. BUNDESEN,* M. D.—There is undoubtedly a great deal in the statement of Professor Winslow that the typhoid rate in the United States is near that of European countries. The rates in this country are probably far closer to the European standards than Professor Winslow's figures would show. In

* Chf., Bureau of Water Safety and Typhoid Control, Dept. of Health, Chicago, Ill.

Europe, where post-mortems are resorted to so frequently, the causes of death are given more accurately and if the same scrutiny pertained in the United States, many communities would have rates of 1 per 100 000.

During the past ten years, tabulation in Chicago, Ill., shows that the average duration of typhoid is 21 days before death. In Chicago, when a typhoid death certificate is presented and the case had not been reported, and if the certificate shows that the person has only been sick two or three days, it is looked on with suspicion and is investigated. Of the ten death certificates held up by the Department during the past several years, the bodies were posted by the coroner, and the cause of death in each instance was abortion or similarly concealed conditions. It would be interesting if Professor Winslow could take the 1916 and 1919 figures which he has presented and ascertain how many of those deaths occurred among patients who had only been sick three or four days.

A question of vital importance to the health authorities of Chicago at the present time, has been presented relative to the use of chlorine in connection with the water supply. More than 500 000 lb. of chlorine are used in a year, and every day more than 800 000 000 gal. of water are pumped. At times, complaints are received regarding the taste of chlorine. The water supplied from Lake Michigan to a community surrounded as Chicago is, must be protected. The water is not filtered and, in consequence, chlorine is used to protect the people. The health authorities have not been able, at any time, to trace any injurious effects to the use of chlorine. It is true that at times people will be told by their family physician that the trouble is due to chlorine, but the speaker is of the opinion that they are simply told this for want of a better diagnosis.

Another feature which might be of importance is the presence of *B. Welchii*, which has been found in the drinking water before chlorination, and at times has been taken from the taps after chlorination. Of course, this bacillus is a spore bearer and is not killed with chlorine.

CHARLES HAYDOCK,* ASSOC. M. AM. SOC. C. E. (by letter).—In the past, the subject of industrial water supply has not received the attention to which it is rightly entitled. During recent years there has been a decided change of opinion coincident with the growing realization of the dependence of many industries on water supply, and the effect that the quality of the water has on the operating costs of such industries. Until comparatively recently only a few industries gave serious consideration to the quality of their water supply, or to the man who, in many instances, realized most forcibly the effect of that quality, namely, the operating engineer whose coal bill was unduly large, whose boiler was pitted unduly, or whose feed-water heaters and hot-water systems were destroyed within a comparatively short time.

Although it is true that the protection of life is the most important function of a water purification plant and, in general, is the fundamental reason for its construction, the chemical effects of the proposed system of purification should be carefully investigated before a decision is made, in order that

* Engr., Water Companies, Philadelphia, Pa.

an unnecessary burden may not be placed on the various industries that will use the purified water. The importance of this feature and the frequency with which it has been disregarded in the older plants can be realized by considering the number of such plants producing an effluent more actively corrosive than the raw water from which it was manufactured. It is also to be noted that the desirable qualities of a water for industrial purposes are not always the same as those for domestic purposes and that the quantities required for the former uses are far greater than for the latter, even in a large city. The use of alum, for instance, increases the hard scale-forming qualities of a water when used for boiler purposes.

The methods of reducing the damage caused by industrial water supplies of poor quality should not be made more difficult by ill-advised treatment designed to render the water safe for domestic uses. Professor Whipple's statement that the elimination of the corrosive qualities of water and the purification of water supplies for industrial purposes is a refinement, is unwarranted, and, fortunately, is to-day held by a decreasing number of individuals. Certainly no one connected with the operation of any industry that uses a material quantity of water will agree with such an opinion.

The classification of waters as "active" and "quiet", or more commonly called "passive", as mentioned by Mr. Hazen, is indeed helpful. In too many cases active waters have been accepted without question, as comparatively few users know that passive waters are obtainable, and, therefore, public sentiment is lacking to compel rendering the waters passive. Active waters constitute a serious handicap to any community required to use them. The corrosive effects in the destruction of service lines, house plumbing, and hot-water piping, are important items of expense in the annual repair bills; after-coagulation is also induced by certain active waters. These effects reduce the capacity of pipe lines to a serious extent, frequently causing the entire stoppage of service lines. In general, the writer believes that it can safely be said that those who are in responsible charge of progressive industrial plants seem to realize the value of soft passive waters to a far greater extent than the designers of many domestic water-treating systems. This has been reflected in the demand for water-treating plants for industries, which, in many instances, use waters already purified for domestic purposes as their raw water supply.

Probably the most dangerous active waters are in the Pittsburgh District.* The value of soft quiet water seems to be more clearly recognized there than anywhere else. Few unpolluted streams are available, practically all the larger watercourses carrying large volumes of coal-mine drainage, which render them acid continuously or, except during the periods of the high spring run-offs. All the major water-using industries in this District find it necessary to maintain water-treating plants which are expensive to operate, but, in some cases, are able to render the waters usable for certain purposes. In the writer's judgment, it can safely be said that from an industrial viewpoint, no treated water is a satisfactory substitute for a naturally pure water supply.

The larger creeks in the Pittsburgh District, in general, are so seriously polluted that no attempt is made to use them. In one instance, a certain

* Recently discussed in the *Journal* of the American Water Works Association.

creek is used for condensing purposes. The tubes of the condensers are of acid-resisting bronze and the body is lined with lead and cement. In some instances, in spite of such precautions, these condensers have been destroyed within a period of three months.

The Youghiogheny River flows into the Monongahela a few miles above Pittsburgh and has a drainage area of 1 732 sq. miles. It is acid practically every day in the year, and has reached a maximum of 22 grains per gal. The Monongahela River, the drainage area of which is 7 340 sq. miles, is very hard, but, in general, is alkaline. Its hardness is greatly increased during periods of low flow and, at such times, it frequently becomes acid. This also occurs following a rise in the river, due to flushing the upper pools. As a safeguard many of the steel mills which use this water for cooling their rolls, add lime, although, in one instance, the quantity used is approximately 100 000 000 gal. per day.

The supply of the City of Pittsburgh, which is taken from the Allegheny River, is of much better quality, but as long ago as 1912, the Managing Engineer of the Municipal Water-Works called attention to the progressive lowering in the alkalinity of this river and the eventual necessity for taking measures to meet this situation. Since that time there have been no very dry seasons. During the first year in which a protractive deficiency of rainfall occurs, particularly if it should be accompanied by high temperatures, no doubt serious difficulties will be experienced in the operation of the Pittsburgh filter plant.

Although these acid waters are highly active, they are practically never used for industrial purposes without treatment, as they would rapidly destroy boilers and all other metallic structures with which they came in contact. It is interesting to note that, in general, waters which are active, but acid free, do not destroy boilers, as the dissolved gases are eliminated rapidly. If a feed-water heater is used, they are almost certain to be eliminated at that point with a consequent destruction of the heater. As an example, it can be stated that in the office building in Philadelphia in which the writer is located, the hot-water piping was destroyed within a comparatively short time and new piping had to be installed, together with a means of removing dissolved gases, which it is hoped will eliminate the corrosion.

The City of Altoona, in Central Pennsylvania, uses a water supply that is acid at all times. This water is practically impossible of use for industrial purposes without extensive treatment, and it is exceedingly expensive to maintain the house-plumbing systems. Meters have recently been installed on all taps, and it will be interesting to note the effect of these acid waters on the meters. It has been proposed to attempt to correct this difficulty by carrying the drainage from the coal mines, which contaminates the supply, below the reservoirs by a sewer. As a result of installing meters, the city supply now has a sufficient margin over the demand to permit this to be done, and according to recent newspaper accounts an effort will be made to compel the mine owners to pay for the cost of this work, which was rendered necessary by their mining operations.

Legal actions to protect the purity of a water supply from contamination by coal-mine drainage are also in process in Fayette and Westmoreland Counties in Pennsylvania. A water company constructed a storage reservoir and an extensive system of piping. Many years later, coal mines were opened above the storage dam. The present litigation has been instituted by the water company and allied interests in an effort to prevent the destruction of its valuable water supply and other properties. This case has been described as the most important pending litigation in Pennsylvania, and its importance is further emphasized by the fact that the Attorney General, acting on behalf of the Commonwealth, has filed petitions for leave to intervene. Argument has been held on these petitions, but so far no decision has been rendered.

The quiet waters between the Alleghanies and Rockies are very hard, and to those accustomed to the softer Eastern waters, almost unbelievably hard. The engineer of water service of an important Western railroad has rather facetiously remarked that some of these waters are so hard that it is customary to analyze them for percentage of moisture rather than for solids.

It is most unfortunate that there is no well established method for treating hard waters satisfactorily. The commoner systems in use simply alter the solids in solution, usually increasing them. Barium is the most common chemical which produces a double precipitation and consequent elimination of the electrolyte, but this treatment is exceedingly costly and the soluble barium salts are poisonous under certain conditions, so that in general this method is not available. If the hardness is high, use of the water for many industrial purposes is prohibitive without some form of softening. This process does not remove difficulties any more than it reduces total solids in solution and, in addition, the use of treated water introduces many problems not encountered in using naturally pure supplies. If the activity of a water is due to acidity, it can be neutralized by the addition of proper chemicals and greatly improved in quality for industrial purposes. This benefit is secured at the expense of an increase in hardness which, at times, may be so great as to be prohibitive, as is the case with so many streams draining the extensively developed coal-mining regions.

The legal aspects of stream pollution are of the greatest importance and are now becoming more widely realized. The Legislative Act creating the Pennsylvania Department of Health, of which C. A. Emerson, Jr., M. Am. Soc. C. E., is Chief Engineer, states in part: "This Act shall not apply to waters pumped or flowing from coal mines or tanneries", thereby eliminating the two industries which have caused the most serious pollution of streams in Pennsylvania. The presence of vast areas of high-quality coal is beyond question one of the foundations of the industrial supremacy of Pennsylvania, and it is unthinkable that legislation should be enacted, which would seriously handicap this vital industry. On the other hand, there are so few unpolluted streams left in the developed coal regions of Pennsylvania that something must be done unless the future industrial development of the State is to be hampered. This condition has become so serious at times that railroads have been greatly delayed in hauling the coal produced by mines which polluted the streams,

the water of which is used for boiler purposes, to such an extent that all the available locomotives were out of service for repairs.

One of the strongest laws on the statutes of Pennsylvania for the prevention of stream pollution by industries is designed to protect fish, and is administered by the Commissioner of Fisheries. In 1915, in addressing the Pennsylvania Water Works Association, the Commissioner called attention to the difficulties of enforcing this Act by reason of the low penalties provided and the unwillingness of Courts to impose these penalties even in the most flagrant cases where conditions could be remedied with comparatively little difficulty or expense. During the last session of the Legislature, an unsuccessful effort was made to amend this Act and raise the penalties so as to permit enforcement of the law. As a result, industrial pollution will continue unabated until at least the next session of the Legislature. Practically all forms of industrial pollution of streams destroy the fish life therein, and the effect of this is to render difficult the enforcement of any of the other laws designed to protect the food and game fishes. This condition was particularly apparent during the low water of the summer of 1921, along the Susquehanna River in the vicinity of Williamsport, when large numbers of fish were killed. As a result, the average individual was unable to see why he should be punished for taking a few game fish illegally when industries destroyed many thousand times more fish without incurring any liability. Any law that is not enforced is a menace, in that it leads to disregarding the law in other cases where the effects of such disregard may be even more serious. Another difficulty encountered by the Commissioner in his efforts to prevent pollution is the lack of a suitable means to treat water contaminated by various industries, chiefly coal mining. It was stated that the managers of many industries were willing to install any system of purification satisfactory to the Commissioner, but as no method was then known or has yet been developed, nothing was accomplished, and he did not feel warranted in closing down the industries until a suitable method was developed.

Referring again to the Pittsburgh District, the Youghiogheny River which is uniformly acid, has been devoid of fish life for many years. The Monongahela is said still to contain a few hardy fish which probably live in the vicinity of the mouths of the purer tributaries. The Allegheny is able to support fish life, as is also the Ohio some miles below Pittsburgh, due to the mixing of the Monongahela and Allegheny. A rise in the Monongahela River, unaccompanied by a corresponding rise in the Allegheny, will flush accumulated acid from the pools of the Monongahela and carry it far down the Ohio to points where the waters are ordinarily acid free. The result of this is that large numbers of fish are killed, and the occurrence of this phenomenon has been reported as far as Cincinnati, Ohio.

Several bills designed to prevent the discharge of oil and oil wastes into harbors and navigable streams were considered by the special session of Congress in 1921. Hearings have been continued and, undoubtedly, similar measures will be introduced later as some legislation is certainly needed to prevent this serious menace to harbors and beaches. These bills are being opposed by

coal operators and manufacturers' associations on the grounds that they might be considered applicable to industrial wastes other than oil sludge. At a hearing, held in Washington on December 7th, 1921, Secretary Hoover testified at length on the seriousness of the situation, recommending that at present legislation be passed applicable only to the oil wastes. Conditions with respect to other industrial wastes, he stated, were so different that they should be thoroughly investigated before any action is taken. The difficulties imposed on communities and industries compelled to use the waters polluted by industries were not brought before the Committee.

Several years ago, the U. S. Engineer's Office at Pittsburgh made an extensive investigation of the acidity of the local rivers, and as a result of that investigation a bill was introduced into Congress to prevent the discharge of acid mine wastes into navigable rivers or their tributaries. Such drastic legislation, naturally, did not pass, but it is to be hoped that, in the near future, some provision will be made for the abatement of what was once a nuisance, but what has now become a menace.

The availability of a satisfactory water supply is an important feature in determining the location of large industrial plants, as is indicated by inquiries received at the offices of industrial agents of large railroads. The report of the recently completed Super-Power Survey recommends that generating stations be built adjacent to the coal mines wherever condensing water is available.

In view of the importance of pure water for industrial purposes, and the lack of satisfactory methods of purification, the writer believes that there is need for research to be conducted on a broad scale and pursued to a conclusion, preferably by some such Federal agency as the Bureau of Standards. An investigation of this nature was conducted by the Pennsylvania Department of Health. As no results were announced, it can be assumed that the investigation was unsuccessful. It was indeed most unfortunate that such an important investigation which was being conducted at such a small cost, should be discontinued on the grounds of economy, as such results are a powerful deterrent to any one contemplating work of this nature.

The greater fall in rural typhoid in the original registration area, as mentioned by Professor Winslow, may have been due to cases carried by media other than water, or to the general rise in the standard of living during recent years.

It has frequently been noticed that typhoid fever in communities served by private water companies is at times charged to the water supply without investigations being made. This has occurred in several instances with which the writer is familiar although analyses showed the public water supply to be satisfactory while analyses of wells and springs used for drinking purposes by many consumers of the water company showed the presence of *B. coli* in very small samples. Fair and impartial judgment would seem to require that all other possible sources of contamination should be investigated, such as milk, ice, ice cream, soda water, raw foods, etc., before the outbreak is charged to the water company.

It is unfortunate that the local physicians do not always aid in quieting the hysteria which so often develops following an outbreak of intestinal disease. Valuable service could be rendered to the communities by calling attention to other sources of possible contamination in cases where the water analyses are satisfactory. In some instances, this, no doubt, would lead to an earlier checking of the spread of the disease.

Paper No. 1489

A REVIEW OF IMPORTANT DEVELOPMENTS IN THE SCIENCE OF CADASTRAL RESURVEYS AS EXECUTED BY THE UNITED STATES GOVERNMENT, WITH ETHICAL DISCUSSION THEREOF

By Howard Richards Farnsworth,* Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. E. M. Douglas, D. E. Hughes, W. J. Lightfoot, Clay Tallman, S. V. Proudfit, H. B. Patten, J. F. Le Baron, and Howard Richards Farnsworth.

Synopsis

Owing to the great number of interesting phases appropriate for discussion in any general review of the science of cadastral resurveys, this work has necessarily been restricted, and is confined to a study of some of the more recent and important of the technical improvements in field and office methods, as developed in the Cadastral Engineering Service of the United States General Land Office.

It must be assumed that the reader is familiar with the long established official method of execution of original public land surveys, which produces a rectangular network of 36 sections per township 6 miles square, with monuments established at intervals of ½ mile. At present, the original areas are nearly all subdivided and platted, and the greater part of what was once a vast undeveloped public domain has passed into private ownership. The rapid development of this area and of its latent wealth depends largely on a quiet title and undisturbed possession which, if not secure, immediately retards the growth of the mineral, lumber, agricultural, and live-stock interests that in large measure form the basis for credit at the banks and that National wealth which is the bulwark of the country.

Until 1910, the Government executed these original surveys by entering into contract with a successful bidder, generally on a mileage basis. An unfortunate result was the frequent careless and sometimes fraudulent work, espe-

* U. S. Cadastral Engr., Gen. Land Office, Div. of Surveys, Washington, D. C.

cially in the early surveys, the natural desire of the deputy surveyor being to execute his contract with the minimum of expense and danger to himself. The early surveys were often a mass of errors, sometimes with no monuments set at all, a fictitious plat and field record having been prepared and filed, which described the true extent and character of the lands represented with only remote accuracy. Again, especially on the Western plains, Nature and the elements have gradually obliterated the corner monuments, important boundaries and whole counties being thus affected. Finally, when settlement began, a vain search for corners commenced, strife ensued, and unending lawsuits developed among the claimants and owners of the lands.

Other great surveying departments of the Government, such as the United States Coast and Geodetic Survey, have always used the most refined methods, a direct method of execution instead of contract, and have taken ample time to measure and calculate distances and angles properly. Yet, when errors are found in their work, no law intervenes to prevent their correction and the moving of the monuments. Corners of public land surveys, however, on which private rights have been based, cannot be changed. Other surveys remain as before, subject only to their scientific authors, whereas the cadastral survey becomes a creature of the Courts.

In order to satisfy the ever-increasing demand for the scientific and legal treatment of this "error", Congress has provided for the Federal execution of cadastral resurveys. For the past eleven years, this complicated and exacting work has been successfully prosecuted by the cadastral engineers of the Government, who are applying only the most approved scientific and legal methods. It is believed that every civil engineer having to do with field work, will find the discussion of the subject, as set forth in this paper, to be of interest and value.

ADMINISTRATION

Organization and Duties

The tenth anniversary of the inauguration of the direct system of surveys and resurveys by the General Land Office was reached on June 25th, 1920, on which date, in 1910, Congress discontinued the old contract system* and the work was placed under the direct supervision of the Commissioner of the General Land Office. The record of all classes of accepted surveys under the new system, for the past ten years, is estimated at 100 109 570 acres, or an average of 10 000 000 acres per annum, the high mark having been reached in 1915. The aggregate area resurveyed during the fiscal year ending June 30th, 1920, was 2 514 306 acres.†

The administration and technical direction of this stupendous work is vested in a small group of civil engineers in what is known as the Division of Surveys and Resurveys. With the advice and counsel of a Board of Law Review, these engineers act for the Commissioner in the attainment of correct

* For an exposition of this system, see the paper by C. L. DuBois, Mass. Inst. of Technology *Quarterly*, Vol. XII, No. 4 (December, 1899).

† Report of the Commissioner of the General Land Office to the Secretary of the Interior, June 30th, 1920, pp. 19 and 127.

execution and practical results in what is undertaken. This Division is the administrative unit which undertakes the administration, supervision, technical control, and execution of the survey of public lands together with other surveys involving the boundaries of Mexican and Spanish private land grants, of State and international boundaries, and resurveys authorized by law.*

Fig. 1 is a diagram of the administrative organization of the Cadastral Engineering Service of the General Land Office as of 1919, showing the relative supervisory responsibilities.

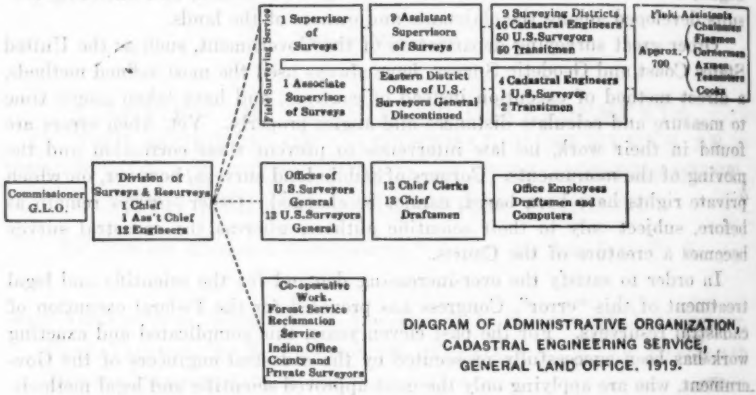

DIAGRAM OF ADMINISTRATIVE ORGANIZATION, CADASTRAL ENGINEERING SERVICE, GENERAL LAND OFFICE. 1919.

FIG. 1.

AUTHORITY OF LAW

In general, the legislation provided by Congress for the execution of cadastral resurveys under this organization may be divided along the lines of the application thereof to two general conditions, first, where title to more than 50% of the land to be resurveyed remains in the United States, in which case the Government bears the entire cost; and, second, where disposals are in excess of 50% of the total area, in which case the private holder bears his share of the expense as well as the Government, proportioned in accordance with the acreage held. This service which has become invaluable to the Western States, has recently been made available to the Central and Eastern States where unending boundary disputes are still found to obtain, although for many years the lands have been held in private ownership.

The first general Act was approved by Congress on March 3d, 1909, and was entitled "An Act Authorizing the Necessary Resurvey of Public Lands." It reads in part as follows:

"That the Secretary of the Interior may * * * cause to be made * * * such resurveys or retracements of the surveys of public lands as * * * he may deem essential to properly mark the boundaries of the public lands remaining undisposed of: Provided, that no such resurvey or retracement shall be so executed as to impair the *bona-fide* rights or claims of any claimant, entry-

* Further information on this subject may be had by reference to the decision of the U. S. Supreme Court in United States *vs.* Morrison (240 U. S., 210–212, inclusive); to the 1919–21 files (Form No. 28), of the U. S. Bureau of Efficiency; and to the report dated March 12th, 1920, of the Federal Reclassification Commission.

man, or owner of lands affected by such resurvey or retracement." (35 Stat., 845).

The second general Act, entitled "An Act Authorizing the Resurvey or Retracement of Lands Heretofore Returned as Surveyed Public Lands of the United States under Certain Conditions" (40 Stat., 965), was approved September 21st, 1918. Work under the latter Act is undertaken on the application of the owners of three-fourths of the privately owned lands, or of any Court of competent jurisdiction.

Restrictions Imposed

From a review of Congressional legislation, it is evident that:

Where private rights have attached to boundaries of the public lands, as duly accepted by the Commissioner of the General Land Office, these boundaries are unchangeable.

Original monuments of all classes on such boundaries must stand as the true corners which they were intended to represent, in so far as such rights are affected, irrespective of whether their actual positions agree with the record of the original field notes.

Where corners on such boundaries have become obliterated or are lost, they must, in a resurvey, be restored in their original positions, according to the best available evidence thereof.

The jurisdiction of final review in all matters of private ownership affected by a resurvey, is vested in the Courts. Thus, it is evident that, in suits involving boundary disputes, the rules of procedure laid down to guide the U. S. Cadastral Engineer in his execution of resurveys must be in harmony with the leading Court decisions, in order that, when properly applied, the Courts may accept without question the boundaries thus determined in so far as they represent the true location of a particular tract of land intended to be conveyed by a patent.

IMPROVEMENTS IN THE FIELD

In Equipment

The modern practices developed and utilized in the execution of Federal cadastral surveys are in keeping with the orderly advance in refinement and precision to be found in the methods used in all other engineering and scientific activities, when compared with the practice of years ago. A 1919 edition of the "Manual of Surveying Instructions", which embraces six of the ten chapters contemplated for the completed edition, completely revises all previous issues with additional new material. This edition has been prepared by a Board, created by the Commissioner, composed of four members of the Engineering Staff of the General Land Office, together with a field officer, which, as a body, deserves much credit for expanding and establishing the practice of a highly specialized science.

A few of the more convenient and useful forms of observation as taken from these recent "Instructions",* will be given in the pages that follow. Some of these forms are not in general use and will appeal to the field engineer.

* "Advance Sheets of a Revision of the Manual of Instructions for the Survey of the Public Lands of the United States", General Land Office, 1919, p. 23.

Alignment

Improved Solar Transit.—The engineer's transit, as equipped with the Smith solar attachment, has been developed in the General Land Office to a state of efficiency which fully warrants the adoption of this model as a standard instrument. In improving the construction, special attention has been given to provide suitable means by which working parts may be properly adjusted to insure uniform accuracy in the results attained. No detail has been omitted, and the perfected arrangement of the working parts permits a precise and rapid adjustment in the field, in a simple manner readily understood by any competent operator and entirely free from any uncompensated or residual errors. Adequate provision has been made for a maximum protection of the delicate working parts, with due attention to compactness and to a proper distribution of weight.

A result of special tests in this service, in which large numbers of every form of solar model are constantly in use, has proven the Smith solar attachment to be far superior in efficiency to all other forms. In improving the construction of this solar attachment to obtain the standard instrument, the process of evolution from the old to the new model has been gradual and tedious, each change being put to the test of months of actual field use.

In the improved construction, a regular light mountain model, full engineer's transit is used, on the east standard of which is mounted the solar attachment. The essential features of the important improvements over older models are as follows:*

1.—The solar has been mounted on an instrument having V-shaped standards, thereby adding much to the stability of the attachment.

2.—The base-plate of the solar is mounted on three foot posts, thus relieving the strain due to imperfect adjustment of the older models having a four-point base.

3.—The position of the base-plate is adjustable by opposing capstan nuts on the foot posts, each with a countersunk ball washer, thereby obtaining positive adjustment altogether free from strain on the capstan nuts.

4.—The three-point base forms a right-angle triangle, with one side horizontal and one side vertical, thereby permitting adjustment in either of two directions: (*a*), One about a horizontal axis, and (*b*), one about a vertical axis, either without disturbing the other.

5.—The axis of the latitude arc is arranged so that its position may be tested with a striding level without removing the auxiliary telescope.

6.—Both the latitude arc and auxiliary telescope are hung beneath the latitude axis, thereby lowering the center of gravity of the attachment and giving much greater protection to the delicate working parts.

7.—Suitable capstan nuts have been placed at one end of the auxiliary telescope to provide for its proper adjustment, with respect to the axis of the latitude arc.

* A. D. Kidder, "A Description of the Smith Solar Attachment, as Recently Improved for the Surveying Service of the General Land Office", published under the direction of the Commissioner, General Land Office, 1915, p. 5.

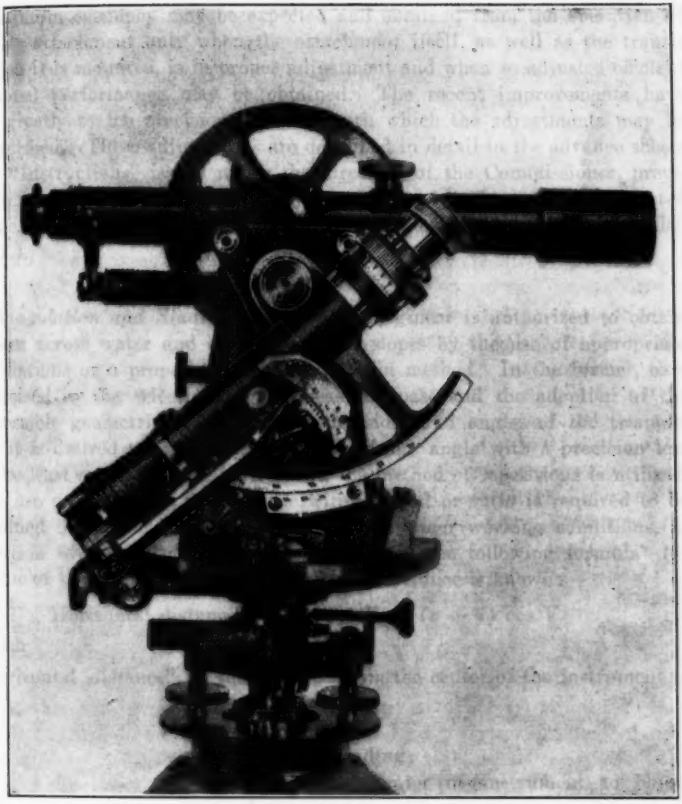

Fig. 2.—The Improved Solar Transit.

8.—Improved interlocking devices have been placed on the latitude and declination arcs, verniers, clamps, and tangent motions.

9.—The mirror may be swung around instantly to permit direct sighting through the auxiliary telescope.

10.—Absolute freedom of motion of the various working parts each to perform its own function, and each one independently, quickly, and permanently adjustable.

Maximum efficiency may be expected and obtained from the operation of the solar attachment only when the attachment itself, as well as the transit on which it is mounted, is in proper adjustment and when so adjusted efficient meridional performance may be obtained. The recent improvements have added greatly to the precision and ease with which the adjustments may be accomplished. These adjustments are described in detail in the advance sheets of the "Instructions" issued under the direction of the Commissioner, previously referred to, and are well worthy of adoption by all engineers interested in time, latitude, and azimuth determinations by the use of this model. (Fig. 2.)

Measurement

Triangulation and Stadia.—The Federal engineer is authorized to obtain distances across water and over precipitous slopes by the use of appropriate triangulations or a properly safeguarded stadia method. In the former, care is exercised in the selection of the measured base and the adoption of the best possible geometric proportions of the sides and angles of the triangle. When it is desired to determine the value of any angle with a precision less than the least reading of the instrument, the method of repetitions is utilized. In the use of the stadia method, the wire interval or ratio is required to be determined in the field by frequent tests and under working conditions, in comparison with steel tape measurement, solving the following formula* for the value of the wire ratio when the horizontal distance is known:

$$\text{Horizontal distance} = K\, r \cos^2 V + (c + f) \cos V$$

in which

"horizontal distance" = the distance from the center of the instrument to the rod;
K = the wire ratio;
r = vertical rod reading;
c = distance from center of instrument to object glass;
f = distance from plane of cross-wires to object glass; and
V = observed vertical angle.

Long Steel Tape and Clinometer.—Where it is possible, the most approved method of measurement, however, is that involving the use of steel ribbon tapes from 2 to 8 chains in length, checked frequently against a suitable reference standard.

* "Tables and Formulas for the Use of U. S. Surveyors and Engineers on Public Land Surveys," Commissioner of the General Land Office, Second Edition, 1913, p. 221.

The long tape when used is properly aligned and stretched so that the measurement may be made on the slope. One of the most rapid and reliable methods of measurement is thus obtained by the skillful use of the long steel tape. The transit is used to determine vertical angles of particularly sharp slopes, the angle of lesser slopes being determined with the clinometer. Slope distances are then reduced to true horizontal distances, and the entire operation is recorded. Rapidity in the reduction of slope measurements is obtained by the use of appropriate reduction diagrams.

In Methods

Beginning with 1890, the inhibition against the use of the primitive magnetic needle for the determination of direction increased, and, in 1894, it was made absolute for all classes of lines on public land surveys. In the execution of the present-day survey, all bearings are determined with reference to the true meridian as defined by the axis of the earth's rotation. Such meridian determinations are required at the beginning, at necessary intervals, and at the conclusion of each work. The instruments are of the latest design and are used only on the approval of a supervising officer after they have undergone a satisfactory test in the field. It is now truly the purpose of the Government to accomplish final results in all its lines of survey, especially in those affecting boundaries of private vested rights.

Different forms of time, latitude, and azimuth observations have been developed and re-arranged to facilitate work under all conditions encountered in the field, most of which are referred either to the sun or to Polaris. Time is readily determined with an error not to exceed 10 sec., while latitude and azimuth are readily available with an error not to exceed 1′ 00″, small errors in assumed longitude being neglected in such determinations.

Some of the more useful of the advances in methods developed and authorized for the execution of official cadastral surveys, as taken from the general instructions issued by the Commissioner of the General Land Office in 1919,* are given in the pages which follow.

Declination.—The advantages of a graphic method for ascertaining changing declinations of the sun, corrected for refraction in polar distance, are to be found in the practical elimination of errors of computation, ease of checking, and in the fact that actual values are obtained without interpolation. This method is illustrated by Figs. 3 and 4. Fig. 3 is a diagram of the sun's declinations for March 20th, 1912; Lat. 37° 30′ N.; Long. 7 hours 30 min. W.:

Declination, Greenwich noon = 4:30 A. M.	=	0° 11′ 14″ S.
Difference, 10 hours = + 593″	=	09′ 53″ N.
Declination at 2:30 P. M.	=	0° 01′ 21″ S.

and Fig. 4 is a diagram of the sun's declinations for September 23d, 1913; Lat. 47° 30′ N.; Long. 6 hours 18 min. W.:

Declination, Greenwich noon = 5:42 A. M.	=	0° 03′ 55″ N.
Difference, 10 hours = — 585″	=	9′ 45″ S.
Declination at 3:42 P. M.	=	0° 05′ 50″ S.

* "Advance Sheets of a Revision of the Manual of Instructions for the Survey of Public Lands of the United States", 1919, pp. 23, 48–49.

In Figs. 3 and 4, the horizontal lines represent each hour of the day, and the vertical lines represent 0° 01′ intervals in declination, the latter being numbered to suit the range of the sun's declination for the date. Two points

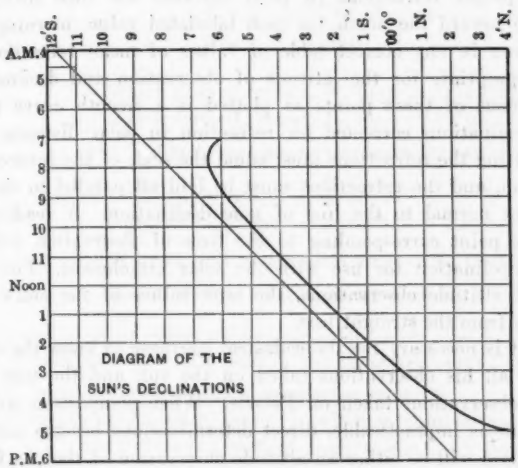

FIG. 3.

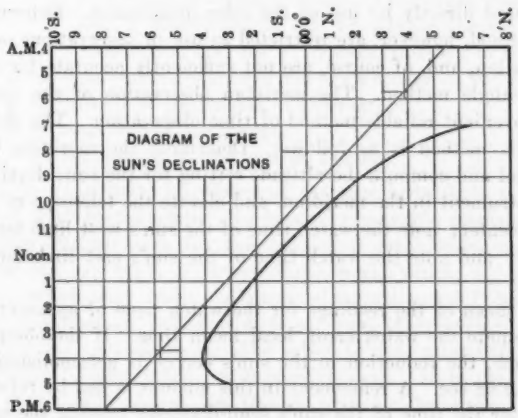

FIG. 4.

are marked on the diagrams to agree with the true declination of the sun. The first point is marked with the argument of declination agreeing with that given in the Ephemeris* for Greenwich apparent noon, that of time agreeing

* "Ephemeris of the Sun and Polaris, and Tables of Azimuths and Altitudes of Polaris", Commr. of the General Land Office, pub. annually since 1910.

with the local apparent time corresponding to Greenwich noon. The second point is marked to agree with the proper declination and time, 10 hours later. A straight line connecting the two points will then form the locus of all points which indicate the sun's true declinations for the date, for local apparent time. The proper refractions in polar distance are then scaled from the straight line toward the north for each tabulated value, morning and afternoon, as given in any correct table of values of mean refractions in polar distance, appropriate for the latitude of observation and declination of the sun. The locus of these points as plotted is a smooth curve representing the sun's declinations corrected for refraction in polar distance. The scale used for plotting the refractions must equal the scale of the intervals of 0° 01′ in declination, and the refractions must be laid off parallel to the horizontal lines and not normal to the line of true declination. A reading from the curve at the point corresponding to the time of observation will then give the proper declination for use with the solar attachment. For use in the reduction of altitude observations, the true values of the sun's declination will be taken from the straight line.

Time.—It is necessary for the cadastral engineer to know the exact apparent time of all his observations taken on the sun and the true local mean time of all observations taken on Polaris. When comparison with standard telegraph time is impracticable, direct determinations become necessary, and the method used will be either an altitude observation of the sun for apparent time, meridian observation of the sun for apparent noon, meridian observation of a star of appropriate magnitude, and declination for local sidereal time, or time secured directly by use of the solar attachment. Determinations by the latter method, however, are restricted to use in observations on Polaris at either elongation, and, of course, are not sufficiently accurate for observations by the hour-angle method. The meridian observation of the sun is by far the most convenient reliable method of time observation. The observing program for this method is as follows: Determine the meridian by the best means at hand and compute the altitude setting for the sun; level the transit, place the instrument in the meridian, and elevate the telescope to the altitude of the sun's center; note the watch time of the sun's west limb tangent to the vertical wire; and note the watch time of the sun's east limb tangent to the vertical wire.

Take the mean of the readings for the watch time of apparent noon from which to compute the watch error, local mean time. If the observation fails for either limb, the reduction to the sun's center is accomplished by adding or subtracting 68 sec. A refinement in this amount is had by reference to the Ephemeris* for the time of the sun's semi-diameter passing the meridian for the date of observation. The setting for the approximate altitude of the sun's center is:†

$$V = 90° - \phi \pm \delta$$

* "Ephemeris of the Sun and Polaris, and Tables of Azimuths and Altitudes of Polaris", Commr. of General Land Office, pub. annually since 1910.

† "Advance Sheets of a Revision of the Manual of Instructions for the Survey of Public Lands of the United States", 1919, p. 65.

The field record appears somewhat as follows:* August 14th, 1909, in latitude 37° 16′ N.; longitude 102° 16′ W.:

Setting:	90° 00′
$\phi \neq$ (—)	37° 16′ N.
$\delta \neq$ (+)	14° 25′ N.
$V \neq$	67° 09′

	h.	m.	s.
°+ Watch time of transit, W. limb =	11	59	22
+° Watch time of transit, E. limb =	12	01	32
Watch time apparent noon =	12	00	27

	h.	m.	s.
Apparent noon =	12	00	00
Equation of time = +	4	33	
Local mean time of apparent noon =	12	04	33
Watch slow of local mean time =	0	4	06

In this and in other observations hereinafter given, the following analytical notation is used, to follow that used in the Commissioner's "Instructions":

Let $\neq$ = an inequality which approaches equality;

V = observed vertical angle; in altitude observations on the sun, the mean observed vertical angle to the sun's center.

h = true vertical angle to the sun's center, or to Polaris, in altitude observations, after correction for refraction: $h = V$ — refraction in zenith distance. In altitude observations on the sun, a refinement is had by adding the value of the sun's parallax = 8.9″ cos V, opposite in effect to refraction.

ζ = true zenith distance of the sun's center = 90° — h.

ϕ = latitude of the station of observation.

λ = longitude of the station.

δ = declination of the sun or Polaris.

Latitude.—A definite knowledge of the true latitude is very important in the use of solar instruments. No lack of reasonable precision is allowed in an accepted latitude and, for this reason, a considerable series of latitude determinations are taken on every large work, which, on comparison, will produce a satisfactory mean. Altitude observations of Polaris at the upper or lower culmination and meridian altitude observations of the sun for latitude are the methods used. The latter is used most extensively, a series of observations being taken on successive days. It is easily executed and appears as follows: Level the transit with the telescope in the meridian elevated to the sun's approximate altitude at noon; observe the altitude of the sun's lower limb with the sun slightly east of the meridian; reverse the transit; observe the altitude of the sun's upper limb with the sun slightly west of the meridian; and take the mean observed vertical angle for the altitude of the sun's center at apparent noon.

* "Advance Sheets of a Revision of the Manual of Instructions for the Survey of Public Lands of the United States", 1919, p. 65.

The field record is as follows:* October 5th, 1909, in approximate latitude 37° 20′ N.; longitude 102° 04′ W.:

Setting:	90° 00′
$\phi \neq$ (—)	37° 20′ N.
$\delta \neq$ (—)	4° 42′ S.
$V \neq$	47° 58′
Lower limb.....	47° 42′
Upper limb.....	48° 14′

$^{\circ}+$ Observed altitude, lower limb, direct = 47° 43′ 00″

$+_{\circ}$ Observed altitude, upper limb, reversed = 48° 16′ 30″

Mean observed altitude,	$V =$	47° 59′ 45″
Refraction	—	0′ 52″
Parallax	+	0′ 06″
	$h =$	47° 58′ 59″
	$\delta =$	4° 41′ 42″ S.
$\phi = 37° 19.3'$ N. $= 90° - \delta - h$	=	37° 19′ 19″
		90° 00′ 00″

Meridian observations of the sun for time and latitude are conveniently combined, by observing simultaneously the sun's lower and west limbs, recording the watch time and the vertical angle, and reversing the transit in the interval of about 2 min., and then observing simultaneously the sun's upper and east limbs. Settings for approximate altitudes of the sun's lower and upper limbs are, respectively:

$$V \neq 90° - \phi \pm \delta \mp 16'$$

Azimuth.—There are a variety of methods and number of heavenly bodies from which to select for determinations of azimuth. A solar transit properly adjusted to the true meridian will serve best on line work in timbered country. In open country, however, it will often be found practicable to carry forward a transit line, always referred to the true meridian by deflection angles. The writer has frequently completed the resurvey of entire townships by deflecting the necessary angles from an initially determined stellar meridian, and when checking the last line run, against the true meridian, has intersected a spade handle set as a reference point. This may readily be accomplished by the careful handling of an instrument which is kept in perfect adjustment.

Methods of observation on Polaris and on the sun are unquestionably the most desirable for determinations of azimuth for the use of the cadastral engineer. Observations on Polaris at its eastern or western elongation, at any hour-angle, most conveniently taken at sunset or sunrise, and direct altitude observations and equal altitude observations of the sun are among those used. The latter method, however, has little adaptability to line work, but by virtue of the need only of approximations of time and latitude, the method possesses a certain usefulness in camp.

* "Advance Sheets of a Revision of the Manual of Instructions for the Survey of the Public Lands of the United States", 1919, p. 67.

By far the most convenient and accurate azimuth determination is by observation of Polaris at any hour-angle, preferably during the daylight hours, thereby eliminating the necessity for artificial illumination and the personal equations of various assistants. However, with the direct rays of the sun above the horizon at sunset or sunrise, a close approximation of the position of Polaris is necessary before it may be found. The hour-angle, t, and azimuth, A, are ascertained in order to locate Polaris in azimuth. Its position in altitude is determined by the following approximation,* the positive sign being used for hour-angles of less than 6 hours and the negative sign for hour-angles exceeding 6 hours:

$$V \neq \text{Latitude} \pm (\text{Polar distance of star} \times \cos t) \neq \phi \pm 70' \cos t.$$

A computation* of the position of Polaris at sunset, May 6th, 1911, at a station in latitude 47° 20′ N., and longitude 102° 40′ W., appears somewhat as follows: The declination of the sun is found from the Ephemeris† to be 16° 18′ N., and the apparent time of sunset is found to be 7 hours 15 min., P. M., by reference to the Standard Field Tables.‡ Then the

			h. m.
Assumed time of observation, May 6th, 1911		=	7 15 P. M.
	h. m.		
Gr. U. C. of Polaris, May 6th	= 10 33.5 A. M.	+	12
Reduced to Long. 102° 40′ W.	— 1.1	=	10 32.4 A. M.
Assumed hour-angle of Polaris west of the meridian		=	8 42.6
Hour-angle, angular measure		=	130° 39′
Azimuth of Polaris, $\neq$ sin	130° 39′		
× (azimuth at W. E.)		$\neq$	1° 17′ W.
Latitude of station	= 47° 20′		
70′ cos t = 70 cos 130° 39′ =	46 (—)		
$V \neq$	46° 34′		

In order to find Polaris an approximate meridian must be available as a reference from which to set off a horizontal angle of 1° 17′ W., and a vertical angle of 46° 34′.

In the twilight hours, after the passing of the direct rays of the sun below the horizon, only a rough approximation of the position of Polaris is necessary in order that it may be found, and there still remains enough daylight for clear identification of the reference mark and reading of the verniers. The writer has often determined the necessary co-ordinates of position roughly from a glance at a Hammet's planisphere set in position for the time and date. Although this method may not at first bring Polaris within the field of the telescope, by small quick movements of the telescope in departure or in latitude, the flicker of the star's light across the field will indicate its presence where a steady, direct sight will not. Especially is this the case when the pre-deter-

* "Advance Sheets of a Revision of the Manual of Instructions for the Survey of the Public Lands of the United States", 1919, p. 100.

† "Ephemeris of the Sun and Polaris, and Tables of Azimuths and Altitudes of Polaris", Commr. of General Land Office, pub. annually since 1910.

‡ "Tables and Formulas for the Use of U. S. Surveyors and Engineers on Public Land Surveys," ed. 2, Commr. of General Land Office, 1913.

mined sidereal focus of the telescope is found not to be true for use on the star. In this observation, a distant object is greatly to be preferred as a reference mark for reading horizontal angles, in order that this focus, when corrected for the star, will not have to be changed when sighting on the mark.

With a number of equations at the disposal of the engineer, to suit his convenience, a very efficient alternative for azimuth observations on Polaris is found in direct altitude observations on the sun. These observations are useful in that they can be taken on the line of survey during the day and used for the required tests of the solar attachment, which during appropriate hours for solar work is expected always to come within 1′ 30″ of the true meridian, before approval.

Under working conditions any line determined with the solar attachment may be used for reference purposes from which to obtain the necessary data for computing the true bearing thereof. In order to guard against error, a series of three altitude observations on the sun, each with the telescope in direct and reversed positions are required. These are readily obtained in 10 or 12 min., while the reductions may be made in the evening. When using this method of observation a full vertical circle, a colored glass shade in the dust shutter of the eyepiece, and a prismatic eyepiece are essential to rapidity of performance and accurate results. The standard improved instrument adopted for use on official surveys has this equipment.

The essential features of this observation consist in the simultaneous determination of the true vertical and horizontal angles to the sun's center. The relation between the calculated azimuth of the sun and the recorded angle to the sun's center gives the true bearing of the fixed reference line. Any one of the following equations* may be entered, and the azimuth of the sun's center as referred to the true meridian at the epoch of observation, may be calculated:

$$\tan \frac{1}{2} A = \sqrt{\frac{\cos \frac{1}{2} (\zeta + \phi + \delta) \sin \frac{1}{2} (\zeta + \phi - \delta)}{\cos \frac{1}{2} (\zeta - \phi - \delta) \sin \frac{1}{2} (\zeta - \phi + \delta)}} \quad \ldots\ldots(1)$$

$$\cos \frac{1}{2} A = \sqrt{\frac{\sin S \sin (S - \text{co-declination})}{\sin \text{co-latitude} \sin \text{co-altitude}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots(2)$$

in which the "pole-zenith-sun" triangle is expressed as follows:

Pole to zenith $= 90° - \phi =$ co-latitude;
Pole to sun $= 90° - \delta =$ co-declination;
Zenith to sun $= 90° - h =$ co-altitude;
$S =$ one-half the sum of the three sides.

$$\cos A = \frac{\sin \delta}{\cos \phi \cos h} - \tan \phi \tan h \quad \ldots\ldots\ldots\ldots\ldots\ldots(3)$$

In case it is desired to obtain both time and azimuth, Equation (1) will be preferred. For a determination of azimuth only, Equation (3) will be found

* "Advance Sheets of a Revision of the Manual of Instructions for the Survey of the Public Lands of the United States", 1919, p. 104.

to be the most convenient on account of the comparative ease of its reduction. An example of direct altitude observation for azimuth on the sun, north declination, using Equation (3) will be given. For a south declination, the function, "sin δ", would become negative by virtue of the sine of a negative angle being treated as negative in analytical reductions; should the algebraic sign of the result be positive, the azimuth, A, is referred to the north point; if negative, A is referred to the south point.

Table 1 gives a series of three direct altitude observations on the sun for azimuth. These observations were taken on August 2d, 1909, at the corner of Ts. 31 and 32 S., Rs. 43 and 44 W., 6th Prin. Mer., Colorado, in latitude 37° 17.5′ N.; longitude 102° 18.6′ W., at 7:30 A. M. apparent time. From a meridian determined with the solar attachment, an angle of 90° was turned to the east. On this line, a flag was set about 20 chains distant, from which as a reference point these observations were taken.

TABLE 1.—ALTITUDE OBSERVATIONS OF THE SUN FOR AZIMUTH.

Series of three observations.	Telescope.	Sun.	Watch time.	Vertical angle.	Horizontal angle from flag to sun.
1st.	Direct	○+	7 h. 36 m. 54 s.	30° 05′	0° 08′ 30″ to N
"	Reversed	+●	7 38 15	29 48	0 33 00 " "
	Mean			29° 56′ 30″	0° 20′ 45″ to N
2d.	Direct	○+	7 h. 41 m. 20 s.	30° 58′ 00″	0° 32′ 00″ to S
"	Reversed	+●	7 43 00	30 46 30	0 12 30 " "
	Mean			30° 52′ 15″	0° 22′ 15″ to S
3d	Direct	○+	7 h. 52 m. 00 s.	33° 08′ 00″	2° 11′ 00″ to S
"	Reversed	+●	7 53 48	32 53 30	1 50 00 " "
	Mean			32° 59′ 15″	2° 00′ 30″ to S

Reduce the mean observed vertical angle to the sun's center for each observation, to the true vertical angle, thus:

	1st Obsn.	2d Obsn.	3d Obsn.
V =	29° 56′ 30″	30° 52′ 15″	32° 59′ 15″
Refraction =	−1′ 40″	−1′ 36″	−1′ 28″
Parallax =	+ 8″	+ 8″	+ 8″
h =	29° 54′ 58″	30° 50′ 47″	32° 57′ 55″

Thence, reducing the first observation of the series for azimuth by Equation (3),

$$\cos A = \frac{\sin \delta}{\cos \phi \cos h} - \tan \phi \tan h.$$

The sun's declination for the mean period of three observations equals 17° 51′ 04″ N.

log cos ϕ = 9.900674	log sin δ = 9.486493 (+)	log tan ϕ = 9.881708	
log cos h = 9.937897		log tan h = 9.759970	
9.838571	9.838571	log	= 9.641678
	log 9.647922	nat (—)	= 0.43821
	nat (+) 0.44455		
	(—) 0.43821		
	cos A = (+) 0.00634		

A = true bearing of sun = N. 89° 38′ 12″ E.
Angle from sun to flag = (+) 0° 20′ 45″
True bearing of flag = N. 89° 58′ 57″ E.

A similar reduction may be made of the second and third observations, for the true bearing of the sun, from which :

By first observation, flag bears N. 89° 58′ 57″ E.
By second observation, flag bears N. 89° 58′ 26″ E.
By third observation, flag bears N. 89° 58′ 38″ E.
Mean true bearing of flag N. 89° 58′ 40″ E.

Therefore, the indicated error of the solar attachment is 1′ 20″.

At any place in the field however remote, the cadastral engineer of the present day is seldom without the means by which to determine true values of time, latitude, and azimuth which are necessary to a correct return of his survey, nor does he often fail to surround his methods with adequate verification in order to insure their required accuracy.

IDENTIFICATION AND RESTORATION OF CORNERS

Permanency of Construction

The boundary lines of the original survey must be retraced and the true bearings and distances between identified original monuments determined before the limits of the areas covered by existing entries and patents may be identified and the computation of the remaining subdivisions of public lands may proceed. Lost or obliterated corners are restored to their true original positions by a proper reference to the original field-note record, influenced in some cases by competent collateral evidences which, before acceptance, however, must be justified in the light of the same record. Monuments restored in this manner, or those identified and reconstructed in place, no longer, as in former days, depend for permanency on shallow pits and mounds of earth with the mythical "charcoal deposit" or, in timbered and rocky regions, on small marked stones of indifferent composition and short-lived bearing trees.

When the true boundary is identified in a resurvey, after many retracements and much investigation, it is now possible to monument the corner permanently by virtue of the Act of Congress approved May 27th, 1908 (35 Stat., 347), and later Acts amplifying this authority. For this, a concrete-filled, 3-ft., iron corner post is used. It may be 1, 2, or 3 in. in diameter, and is set in

the ground with the fill tamped in over a broad flange at the bottom. If the soil is sandy and loose, the flange of the post is set in a concrete base. This post is then witnessed by the best of available accessories, such as marked bearing trees, pits, or mounds of stone. The corner position is carefully re-monumented without destroying the physical evidence which served to identify its original position, the utmost regard being shown for all such evidences of original location. A complete record is kept of the description of the original marks as identified and all the resurvey additions thereto. At the time they are used, the brass caps of the iron corner posts are suitably and plainly marked with steel dies, capital letters and Arabic figures being used. Fig. 5 shows a sample marking of brass caps. As an additional safeguard to insure the permanency of these monuments Congress, by an Act approved March 4th, 1909 (35 Stat., 1088, Sec. 57), has provided a fine and imprisonment for those who wilfully destroy them or effect their removal.

Recognition of Physical Evidence

The Courts attach major importance to authentic evidence relating to the original position of an official corner monument, such evidence being given far greater weight than the technical record relating to bearings and lengths of lines. The legal signficance of original monuments makes it mandatory on the engineer to exercise the greatest diligence to find and restore each corner in its true original position. On the treeless prairies of the Central Western States where original corners were generally constructed of wooden posts or small stakes with pits and mounds, the writer has identified and reconstructed hundreds of such monuments long obliterated and considered lost, by the ordinarily simple, but sometimes very expert, process of removing the top sod or soil with a sharpened spade and revealing the distinct outlines of the original pit beneath, in the exact form as left by the builder years before. The original pit has gradually filled with blowings and wash of a distinctly different nature from the homogeneous soil on all its sides. During many years of experience in this work, the writer has recovered indisputable outlines of such original pits under all conditions and kinds of soil—in roadways, on steep slopes, and on lands subject to overflow—and he has no hesitation in stating that when once dug if any part of the original sides of the pit still remains, the fill in the center can be identified with certainty by this method.

In timbered regions where Nature has healed the wounds made by the scribing tool of the original surveyor on the tree corner, or the "bearing" trees used as accessories to the corner, the expert will readily identify the new growth over the old blaze. A sharp axe applied above and below the growth will remove it in one piece, thereby uncovering the marks originally made on the tree itself and also those transferred to the piece removed, where they will appear raised in relief. Furthermore, removal of such growths from the old "line" trees and others of those which may mark the section line, will often reveal the old axe marks. This evidence, when corroborated by a correct "ring count" in the growth itself, will provide silent but convincing testimony

as to the position of the original line, even when the corner monuments themselves cannot be found. Illustrations of such growths, which were removed by the previously described method from the original blazes and on which the original marks appear in relief, will be found in Figs. 6 and 7. Fig. 6 shows a chip from a white fir tree which in the original survey of the boundary line between the States of Oregon and California was marked and described by Deputy Surveyor Major in 1868, for the 147th-mile corner. This fir tree was readily identified 47 years later—in 1915—by cadastral engineers in a resurvey of this line. The growths over the original blazes were removed, and the tree was found to be correctly marked, as follows: 147 M on the east; O on the north; C on the south; and 42 L on the west faces of the tree.

The chip shown in Fig. 6 is from the west face of this tree. It plainly shows the original marks, "42L", in relief, and is made up of forty-seven growth rings, corresponding to the interval in years which had elasped since the date of the original survey. In Fig. 7 will be seen a part of the growth removed from over the original marks on a cypress bearing tree at a meander corner on the line between Sections 32 and 33, T. 41 S., R. 37 E., Tallahassee Meridian, Florida. Originally, the thickness was a few inches greater than that shown in the photograph, the outside portion having been lost in the removal. The marks which plainly show in relief, were made on the tree in 1855, and the chip was removed by cadastral engineers in 1919. The "ring count" on the adjacent growth was "sixty-five", which was the correct time interval in years.

An interesting example of a restoration involving the identification of original bearing and line trees and the proper application of proportional measurement occurred in 1913, in the oil district of Louisiana, in the determination of the section and subdivision of section lines of Section 3, T. 20 N., R. 16 W., L. M. The methods used were thoroughly tested in the trial of a boundary suit where a difference of 1.7 ft. involved a property value exceeding $800 000. Many days were required in the trial to hear the technical evidence alone. The following extract from the decision of the Supreme Court of Louisiana (No. 22 485, February 25th, 1918), is illustrative of the severe requirements of such restorations:

> "Among the several surveys made, one stands out as most worthy of consideration by the Court. It was not made on behalf of any of the parties interested in this litigation, but it was ordered by the United States Government and it was executed under instructions from the General Land Office, whose stamp of approval has been placed upon it. Under these circumstances, the recognized ability and competency of the engineer, the total absence of any possible bias on his part, the great care he exercised in the performance of his work, the most modern and scientific methods adopted by him and the further fact that the result of his work bears the approval of the General Land Office, are, in our opinion, sufficient to establish a preponderance of evidence in favor of plaintiffs and to justify a decree based upon his findings under the law applicable in the case."

Methods of Restoration

The original corners restored in a resurvey may be divided into two general classes: (*A*) those identified and reconstructed in place; and (*B*) those

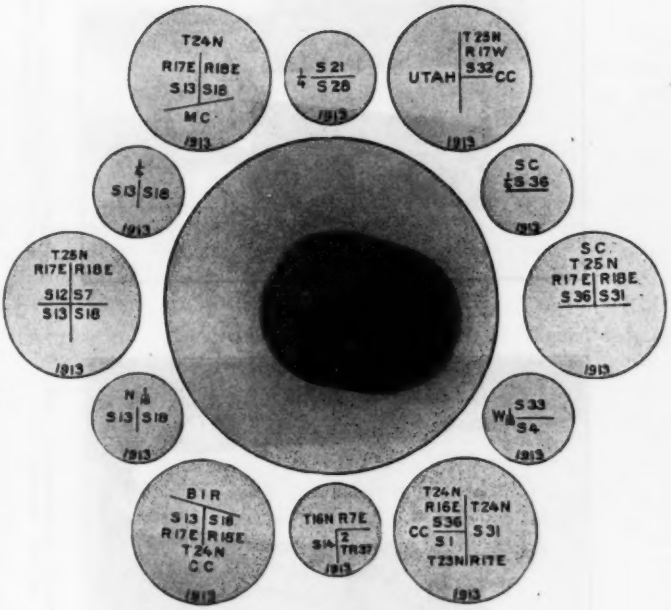

FIG. 5.—SAMPLE MARKINGS OF BRASS CAPS.

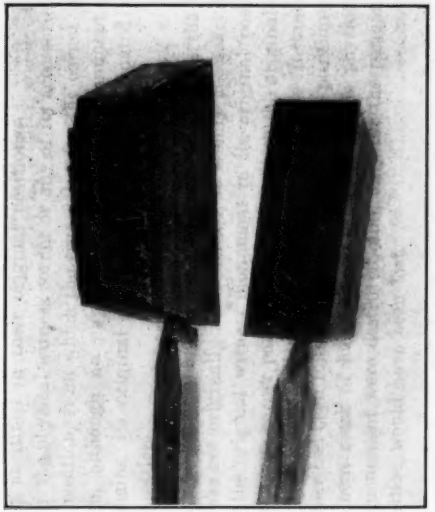

FIG. 6.—OVERGROWTH TAKEN FROM WHITE FIR TREE CORNER ON OREGON-CALIFORNIA STATE BOUNDARY.

FIG. 7.—OVERGROWTH TAKEN FROM CYPRESS BEARING TREE IN FLORIDA.

restored by a mathematical or ethical procedure. Further defined, they will appear as follows:

(*A*).—A corner is identified and may be reconstructed in place:

1.—When the physical monument itself or any of its accessories are found and identified in their original positions.

2.—When the physical witness corner or any of its accessories are identified in position, from which the true point for the corner is determined.

3.—When, although no physical trace of the monument or accessories remains, its original position has been perpetuated with certainty by settlers.

Referring to Paragraph 2, it naturally follows that, as the true point for the corner was not originally monumented, it is only necessary in such a case to identify the original witness monument in its original position and then proceed to the true corner point in accordance with the original record.

Identification under Paragraph 3 includes those instances where the original corner had been found at one time and its true position perpetuated by some permanent mark of local origin, after which the physical evidences of the official monument were destroyed, and, only for the permanent mark, the original position would have been lost.

(*B*).—A corner is identified and may be restored to place:

1.—When an appropriate reference is made to the original record, from which is established a definite relative position with respect to other adjacent and existing competent points of control, as follows: (*a*) other existing public land corners; or (*b*) corners of other systems of surveys or unchanged and definite original points of topography.

2.—When a position has been recognized for years as the location of the corner by all who reside in the vicinity, and has been agreed on and perpetuated as such by the several parties in interest; such point, however, must hold an acceptable relative position when compared with those original official monuments within the field of influence of which the point is found to be situated.

The method of Paragraph 2 under Heading, (*B*), does not imply necessarily that such position has any direct relation whatever to the true position of the corresponding original monument itself. Unusual cases will also arise where the nearest existing original corners are so far distant (all intervening monuments having been lost) as to lose in some measure their influence and value as factors of control. In this event, other competent collateral evidence will correspondingly increase in relative value for the identification of an acceptable position for the corner.

A choice must always be made between the several methods of restoration. The appropriate method will depend, of course, on local conditions existing in the particular case under consideration, selected so as to afford an equal protection for all the interests involved. To accomplish this result, it does not always follow that the most probable position of the lost original monument

will be the one accepted when a proper consideration and combination of all available evidence is made. When the physical corner itself has once been destroyed and the original position lost, any method selected by which to restore it to its most probable position will not do so with certainty. It is better at once to adopt the position with respect to the nearest existing corners which has the greatest possible concordance with the original record, as all disposals of public lands are made in accordance with the original plat representing such record, both as to the position and extent of land intended to be conveyed. This is exemplified in the method ordinarily proper for the restoration of closing corners in cases where the closing line defines the boundaries of alienated lands. In such cases, the identification may be made by means of a proportional measurement based on the plat distances to the right and left of the closing corner, measured along the line closed on, rather than on the single record connecting tie of the original surveyor alone; also, the same reasoning applies in the identification of those lost corners immediately preceding on the closing line, namely, the lost corners on a range line closing on a standard parallel, the identified positions of which ordinarily are based on a proportional measurement extending to the major line closed on (standard parallel), and not to the original closing monument itself, in cases where the monument is known and is off the major line.

Proportional Measurement

The method given under Heading (*B*), Paragraph 1, is, in general, that method ordinarily referred to as "proportional measurement", by which is meant a measurement having the same ratio to that recorded in the original field notes as the length of the line by re-measurement bears to its length as given in the record. The ideal condition, of course, would be that in which the corners chosen as a basis for control would occupy in all directions the position they should with respect to each other without any excess or deficiency; however, such is rarely, if ever, the case. The evidences of position offered by these controls are always conflicting to a greater or less extent, but as they are of the same type and as controlling factors vary inversely as the distances involved, these evidences, although conflicting, may be consistently combined and, at the same time, admit of a practical and more or less general application. This has resulted in what is called the single and double proportionate method, on which, it has been found, dependence must be placed in the execution of resurveys for the major number of restorations, and with respect to which the only general rule of procedure has been formulated.

An exception is made, however, to any such general rule of proportion in those cases where, on account of the existence of gross error and irrelation in the evidences of the original survey, or, in the presence of extensive obliteration, only one or only two of the nearest existing original corners have been used by entrymen for the control of locations where more controlling points should technically have been considered. The location of such a claim, so determined and perpetuated by improvements, will often differ materially from that determined by a proper consideration of all the existing corners, that is,

two or four. In such cases, it cannot generally be charged that a lack of good faith has been shown, and those acceptable positions for the lost corners as fixed by evidences of occupation are then adopted for the identification of the tract and possibly for other tracts which may be in harmony therewith. In these cases of irrelation, natural conflicts will often be found to exist and must be recognized and identified on the ground by the engineer for adjudication by the proper Court. These locations are best identified in the form of tract segregations by metes and bounds in "independent" resurveys, further consideration of which will follow.

Theory of Non-Concurrent Parallel Forces

On all lines of the same class in any survey, each call of the original record should bear, theoretically, its proportion of responsibility for discrepancies found to exist between evidences of such survey on the ground and the record thereof, and the errors should vary directly as the distance, along any line of such survey, of an identified control away from the locus of the lost corner. For example, if five or more monuments had been established originally, one of which is assumed to be lost, its restoration might be based on a consideration of as many temporary points as there are existing monuments, each temporary point to be assigned its proper value or weight and to be located by proceeding on the record course and distance from one of the existing monuments. The temporary points thus determined might then be treated as a system of non-concurrent parallel forces acting normal to a horizontal plane, the position of the resultant of which is sought for the position of the lost corner. The restoration would be accomplished by assigning to each temporary point a value inversely proportional to its distance from the initial existing monument at the other end of the random line. Obviously, this academic reasoning could be applied in any practical restoration of public land corners only as between the nearest identified corners in any direction, in order to avoid a needless multiplicity of temporary points. If it could not be assumed that those corners which are situated outside of a certain restricted field of influence, are at so great a distance away as to have little or no effect, it at once becomes evident that a strict adherence to the foregoing principles would have no value for a practical application.

Fig. 8 illustrates the theory of non-concurrent parallel forces, as applied from a four-point control, for example:

Let *A*, *B*, *C*, and *D* represent four identified bearing trees witnessing the position of a corner of the original survey; also, let *a*, *b*, *c*, and *d*, represent four corresponding temporary points for the restored corner, the positions of which are determined by the courses and lengths given in the original record as run from the identified original bearing trees, *A*, *B*, *C*, and *D*.

Since *C* and *D* are distant from *c* and *d* only one-half the distances of *A* and *B* from *a* and *b*, the temporary points *c* and *d* will be assigned a measure of influence (or weight) twice that of *a* and *b*.

Therefore, with *a* and *b* each valued as 1, *c* and *d* will each be rated as 2. As the values of *c* and *d* are equal, which is also true of *a* and *b*, the combined influence of each pair may be represented, as to *c* and *d* by

a temporary point, *e*, mid-distant on Line *cd*, with a weight of 4, namely ($e = c + d = 2 + 2 = 4$), and as to *a* and *b* by a point, *f*, mid-distant on Line *ab*, with a weight of 2, namely ($f = a + b = 1 + 1 = 2$). Thence, the true point for the restored corner which results, with due regard for the influence of each bearing tree, will lie on a line connecting *e* and *f*, a distance from *f* to *e* equal to two-thirds of the total, namely $\left(\frac{4}{2+4} = \frac{2}{3}\right)$.

The resultant point on the line, *ef*, will be removed, therefore, from *e* or *f* distances which assume an inverse ratio to the respective weights assigned thereto. Any combination of the points, *a*, *b*, *c*, and *d*, with properly assigned weights, will give the same resultant position for the true corner.

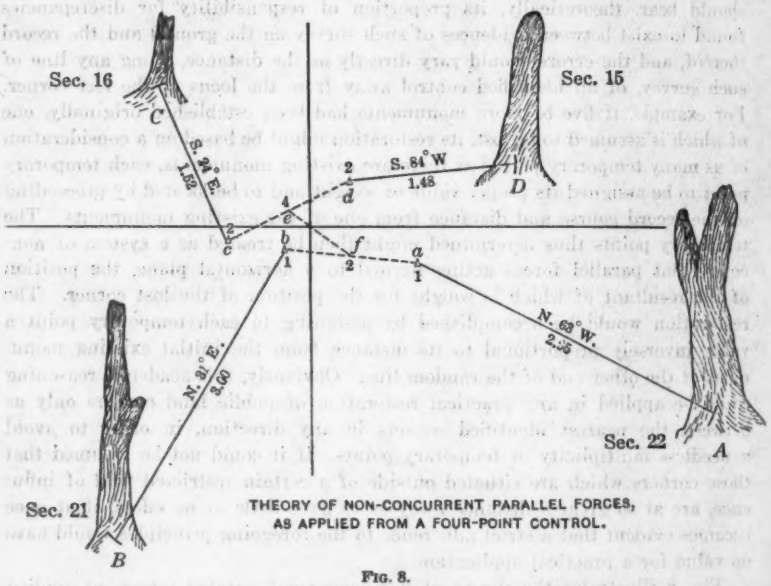

FIG. 8.

Application of Theory to Broken Boundaries.—The restoration on the ground of any angle-point of a meander line, between the two nearest meander corners, would appear in the execution somewhat as shown in Fig. 9.

Let *A* and *B* represent, respectively, a re-established and a reconstructed original meander corner on the east and west boundaries of Section 28. The numbered lines, 1, 2, 3, and 4, and 6 and 5 represent consecutive meanders run out from *B* and *A*, respectively, on the record course and distance, to arrive at the temporary points, *b* and *a*. Then, the restored position for the desired angle-point will be on the line, *ab*, a distance from *b* represented by the fraction,

$$\frac{1+2+3+4}{1+2+3+4+5+6}$$

in which the numerals represent the record lengths only of the correspondingly numbered meander lines.

Similarly, all the angle-points of such a line may be reproduced on the ground by running out the complete record from either B or A, as shown graphically in Fig. 10.

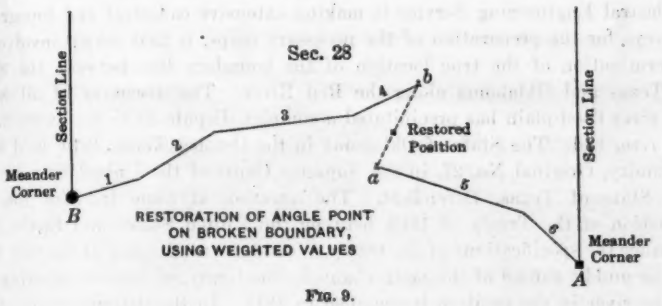

FIG. 9.

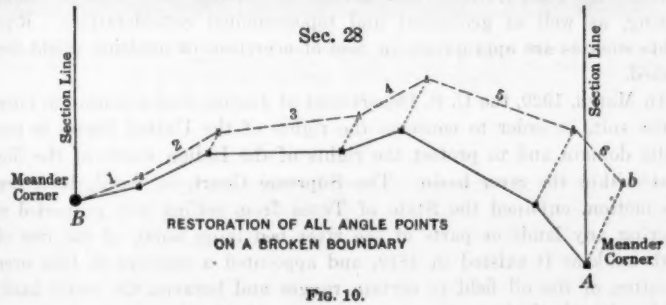

FIG. 10.

In Fig. 10, the closing error, Ab, is by construction equal to the length, ab, in Fig. 9. To effect a restoration of the entire meander line in Fig. 10, lay off from each temporary angle-point in the direction and on a line parallel to Ab, a distance which will be a proportional amount of the length of the closing error. This distance will be that one which is to the whole length of the error (Ab) as the distance of the particular temporary point from the initial point (B) is to the whole length of the meander line (from B to b). If one or both of the meander corners on the section lines are lost, they are first restored, before proceeding with the reproduction of the meander line.

Lost corners originally established in metes and bounds surveys, and all other irregular surveys not of the regular rectangular system, broken controlling boundaries, and the angle-points of a meander line, are restored and reproduced on the ground according to the principles as described. A valuable discussion* by Leonard S. Smith, M. Am. Soc. C. E., of a similar method of restoration of a broken boundary in which the problem was the retracement

* *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 429.

of an old road, will be found to be of great interest to those in contact with this subject. In this case, the "twist" or error in azimuth of the original surveyor's meridian was computed and also the ratio of the lengths of the original and the resurvey chains.

Oklahoma-Texas Boundary Controversy.—A very important boundary dispute of related interest, now in litigation, and one in which the U. S. Cadastral Engineering Service is making extensive cadastral and topographic surveys for the preparation of the necessary maps, is that which involves the determination of the true location of the boundary line between the States of Texas and Oklahoma along the Red River. The discovery of oil within the river flood-plain has precipitated a complex dispute as to the ownership of the river bed. The State of Oklahoma in the October Term, 1919, filed a suit in equity, Original No. 27, in the Supreme Court of the United States *versus* the State of Texas, Defendant. The question at issue involves the construction of the Treaty of 1819, between the United States and Spain, as to whether the specifications of the treaty refer to the south bank of the Red River or the middle thread of the main channel—the treaty, of course, referring only to the river in the position it occupied in 1819. In the determination of this position, the comparatively new science of Ecology* will have an important bearing, as well as geological and topographical considerations. Riparian rights such as are appropriate in case of accretion or avulsion might then be applied.

In March, 1920, the U. S. Department of Justice filed a motion to intervene in the suit, in order to conserve the rights of the United States to possible public domain and to protect the rights of the Indian wards of the Government within the river basin. The Supreme Court, in April, 1920, granted this motion, enjoined the State of Texas from selling any purported rights covering any lands or parts of the river bed lying north of the line of the south bank as it existed in 1819, and appointed a receiver to take over the operation of the oil field in certain ranges and between the south bank and middle thread of the main channel of the river. A suit was subsequently filed in the U. S. Federal Court for the Western District of Oklahoma, by the Department of Justice, in behalf of the Indian allottees, in order to protect riparian claims attached to Indian allotments on the north bank and extending to the medial line between the river banks (the present meander lines of the right and left banks), which according to the Indian treaty of 1867, is the line designated as the south boundary of the Kiowa and Comanche Reservations. The District Court has appointed a receiver to take over the operation of the oil field within the riparian claims of the Indians. The receiver for the Supreme Court under a working agreement has control of any areas in conflict between the two receiverships.† Separate consideration will be given in these suits to the questions of fact as to the positions determined for the true boundaries at the definite dates. A reference to Figs. 11 and 12 will give the reader a very good idea of the appearance

* Plant Ecology: the Adaptation of Plants to Life Under Particular Environing Conditions; one of the chief exponents of the science in the United States is Dr. Henry C. Cowles of the University of Chicago.

† Report of the Commr. of the General Land Office to the Secretary of the Interior, June 30th, 1920, pp. 33–34.

FIG. 11.—RED RIVER, LOOKING NORTH FROM TEXAS SIDE. IRREGULAR FULL LINE INDICATES POSSIBLE POSITION OF 1819 RIVER BANK. DASHED LINE SHOWS SOUTHERN LIMIT OF AREA UNDER SUPREME COURT RECEIVERSHIP.

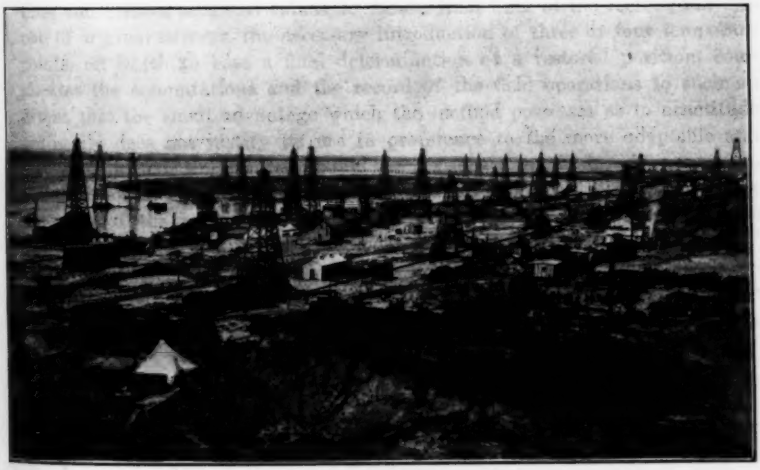

FIG. 12.—RED RIVER, LOOKING NORTHEAST FROM TEXAS SIDE. FULL LINE INDICATES POSSIBLE POSITION OF 1819 RIVER BANK. DASHED LINE SHOWS SOUTHERN LIMIT OF AREA UNDER SUPREME COURT RECEIVERSHIP.

of the oil field under the receivership. Fig. 11 is a view of the Red River, south of T. 5 S., R. 14 W., I. M., Oklahoma, looking north from the Texas side. The irregular full line indicates the possible position of the 1819 river bank, and the dashed line shows the southern limit of the area under the Supreme Court Receivership. Fig. 12 is a view of the Red River, south of T. 5 S., R. 14 W., I. M., Oklahoma, looking northeast from the Texas side. The full line indicates the possible position of the 1819 river bank. The dashed line shows the southern limit of the area under the Supreme Court Receivership. As the bed and flood-plain of the river are located over an oil "dome" or pool, nearly every well has been a producer and property values exceeding $100 000 000 are involved in this boundary litigation. The photographs were taken during 1920.

Erroneous and Fraudulent Meander Lines.—Meander lines as shown on approved plats are sometimes erroneous or fraudulent. In these cases, the lines as recorded do not and never did conform even approximately to the mean high-water elevation of the actual body of water, and, thus becoming fixed boundaries, they sometimes omit large areas of public land from the original surveys. The location of a true mean high-water mark as of an early date, for critical comparison with the restored record position of the original meander line, overlaps somewhat into the realms of geology and ecology. These questions while involving the tracing of old escarpments in the soil and investigations into the age and growth of trees, are not overlooked by the cadastral engineer.

In the practical application of the foregoing mathematical method of restoration, which contemplates the use of both lengths and courses of original lines and utilizes weighted values, to the cardinal lines of the rectangular system of original surveys, the necessary introduction of three or four temporary points, on which to base a final determination of a restored position, complicates the computations and the record of the field operations to such an extent that the small advantage which the method possesses as to exactitude ordinarily does not justify its use in preference to the more adaptable and less complicated single and double proportionate methods of restoration. Except in cases where excessive distortion is developed, all restorations along the lines of the rectangular system will yield readily and logically to the principles involved in the latter methods. Although both the "weighted value" and the "double proportionate" methods depend on the same general underlying principles, the latter, although less theoretical, will produce results equally as good and is more practical of application than the former method, and has been adopted for official use.

Single and Double Proportionate Methods

The single and double proportionate methods of restoration are based on a consideration of the record distances only, the record courses in all cases being ignored, the measured distance between the two nearest existing corners being divided into distances proportional to those given in the record between the same corners. A necessary advantage of this method over that of the "weighted values" is that the restoration of one lost corner may be based on

the restored position of any other lost corner without producing the incongruities which will develop occasionally in using the method by "weighted values".

In explanation of the "double proportionate" method as now adopted for official use, assume that the problem is the restoration, from a four-point original control, of a lost section corner on the rectangular subdivisional lines of a township survey. A retracement is first made on the meridional line connecting two of the original corners, on which line a temporary stake is set at the proper proportionate distance, based on the original record. This point will determine the latitude of the lost corner. Next, the two original corners remaining are connected by a latitudinal retracement and a corresponding temporary stake set thereon, determined by proportionate measurement in a similar manner. The second point determines the position of the lost corner in departure. The intersection of two cardinal offset lines run from these two temporary stakes, north, south, east, or west, as relative situations may determine, will then define the restored position of the lost corner. The obliquity of the section lines in their restored positions, such as occasionally results, suggested some years ago the application of a slightly different method of proportionment based on those field distances which are measured along the hypotenuses of the several right-angled triangles created instead of along the long legs. This method when utilized provides an interesting and intricate mathematical study and, in the past, has required of the writer many days of harrowing field computations for its application. However, the impracticability of this method for general use is now admitted, inasmuch as the time-consuming field operations, extra computations, and complications of the record have proven wholly incommensurate with the doubtful degree in equity attained. Restorations are designated as "single proportionate" when made on lines established with reference to a definite alignment in one direction only.

IDENTIFICATION OF ALIENATED LANDS

General Principles

The fundamental principles used for the protection of *bona-fide* rights under the law are identical in all types of resurveys. In the case of the identification of the original position of any tract of land to which private rights have attached under the original survey, the identification when completed is regarded as a demonstration on the part of the General Land Office, in the light of the best evidence available, of the original position of those entered or patented subdivisions which are included in the description of the entry or patent, all as referred to the original survey. The cadastral resurvey, as far as private rights are concerned, has no creative function of its own, and it cannot change or supersede a completed function of any monument of the original survey. It must accept, without change, these original evidences of location as they are found to exist. Before a settler who "squats" or establishes residence on unsurveyed land, may make entry in accordance with

the legal subdivisions of an official plat after the land has been surveyed, he is required to adjust his lands to the descriptions and lines of the official survey. The settler who establishes himself on lands already subdivided and platted has the advantage of the "squatter", in that he has the original corners and an original record at his disposal to facilitate the proper location of his lands. Naturally, no less is required of the entryman on surveyed lands, who has monuments and an original record to guide him, than is required of the "squatter" on unsurveyed lands who has none; for the lands of the former are also required to bear an acceptable harmonious relation to authentic evidences of the original survey, in accordance with which his entry was made. For example, if a settler makes entry for lands described in Section 5 and then establishes his residence and erects improvements not on Section 5, but somewhere on Section 7 or Section 17, his location is clearly erroneous under his original description, and, therefore, the description of his lands must be changed if he is to obtain a clear title to those legal subdivisions actually occupied. If a patent has been issued under the erroneous description, a corrected patent may be issued on a proper showing in lieu of the original. This may only be accomplished in accordance with the regulations issued under authority of the legislation providing for amendment of entries (Act of February 24th, 1909, 35 Stat., 645).

Bona-Fide Rights

Thus, the cadastral engineer of the Government draws a clear distinction between the *bona-fide* rights as to location and as to occupation. Only with the former is he directly concerned, for the rights as to occupation are without his province and are entirely within the jurisdiction of the adjudicators of the proper court of law. If an entryman finds that his lands are erroneously located, his relief may be found only in accordance with existing law and not in any particular inspiration of a surveyor. However, in the case of irrelation and obliteration of corners of the original survey, where any one of several possible original positions is acceptable, that acceptable position is used which more nearly than any other covers the lands actually occupied and improved; in other words, the improvements are taken to indicate the particular original corner or corners which are to be used to control the position of the lands. The definition of good faith in location, as furnished the cadastral engineer by the Commissioner of the General Land Office, is necessarily broad, as witness the following:*

"It may be held generally that an entryman has located his lands in good faith * * * when it is evident that his interpretation of the record of the original survey as related to the nearest existing corners at the time the lands were located (as defined by his fencing, culture, or other improvements) is indicative of such a degree of care and diligence upon his part, or that of his surveyor, in the ascertainment of his boundaries, as might be expected in the exercise of ordinary intelligence under existing conditions."

* "Advance Sheets of a Revision of the Manual of Instructions for the Survey of the Public Lands of the United States," Commissioner of General Land Office, June 16th, 1919, p. 278.

In the application of this definition to field conditions, the U. S. Cadastral Engineer has become properly impressed with the purpose of his task and the stability and dignity which is attached to a work so great and important, commensurate with the broad foundation in science and law. The records of a cadastral resurvey must form an enduring basis on which depends the security of the title to all lands acquired thereunder, and the field notes must be prepared so that under the test of the closest possible scrutiny at all times, present and future, the record can be regarded as conclusive in the matter of the proper location of private rights.

General Types of Resurvey

In general, any field condition that may arise will yield properly to the application of either of two recognized methods of executing Government resurveys, namely, the dependent or independent resurvey.

The Dependent Resurvey.—The typical dependent resurvey may be defined as an official re-marking on the ground of all the original section lines in their original positions, in accordance with the best available evidences thereof, in such a manner that all original subdivisional units, as identified, will occupy those positions which result from a proper legal subdivision of the sections thus restored. It is obvious that this type of resurvey is chiefly applicable to those cases showing a fairly concordant relation between conditions on the ground and the record of the original survey, for titles, legal areas, and descriptions are maintained as unchanged. The primary control for such a resurvey is based, first, on identified existing corners of the original survey and other acceptable points of control; and, second, on the restoration of missing corners by proportionate measurement in harmony with the original record.

The Independent Resurvey.—On the other hand, in areas where gross error or irrelation is present, as between the existing evidences of the original survey, a zone of uncertainty often exists wherein the strict application of proportional measurement is either impossible or entirely inadequate for the protection of rights acquired in good faith under the law. In such cases, segregation of private land claims by metes and bounds surveys with a suitable tract number, from a one-point control according to the original record, is often necessary, or the conformation of such claims to the lines of an independent resurvey under either the original or new legal subdivisions, as may be appropriate; in either case, however, the claim as identified will occupy an acceptable position when referred to suitable evidences of the original survey. In such cases, there is generally no necessity whatever of applying any original restorative process for the description of the remaining unclaimed public domain, and an independent resurvey is executed in accordance with the cardinal lines of the official rectangular method of subdivision which, as to the vacant public domain, then supersedes the record of the original survey. In this type of resurvey, in cases where original descriptions are changed, the descriptions under the resurvey (tract segregations, or legal sectional subdivisions) and under the original survey of all private claims are appropriately shown, cross-referenced in an index table on the plat, and, in all

cases, existing private claims are blocked out in place and designated on the plat for further identification.

With respect to the protection of *bona-fide* rights, the basic principle is identical in either the dependent or independent type. In the former, all the lands patented and entered are identified theoretically by the legal subdivisions of the exhibited sections; in the latter, the identification is accomplished either by tract segregations or by conformations of the private claims to the sectional subdivisions, under either the old or new descriptions.

On Plate V is shown the resurvey of T. 27 N., R. 40 W., 6th P. M., Nebraska, which embraces boundary lines exemplifying both the dependent and independent types of resurvey, the limiting boundary between the two being along the original eastern boundaries of Sections 3, 10, 14, 23, 26, and 35, and the northern boundary of Section 14. The sectional lines in the dependent portion are covered by a resurvey, as shown on the plat approved October 4th, 1883, in their original positions according to the best available evidence of the positions of the original corners; all differences between the measurements shown on the original plat and those derived in the retracements have been distributed proportionately between accepted corners in accordance with surveying rules. The sectional lines shown in the independent part are not established on cardinal courses with regular corner spacing as is generally the case when this method is utilized, for by reason of a condition peculiar to this locality they were retained as delineated in the field, on a basis of proportional measurement against the "limiting" boundary. The plat does furnish, however, a normal example of the conformation of several entries to the lines of the resurvey under their original descriptions, and also exhibits various metes and bounds surveys which have been executed by the use of a one or two-point control. In Table 2 will be found the necessary information as to the segregated tracts, and in Table 3 areas of the various conflicts and exclusions are given. The method shown of treating the areas in conflict provides a comprehensive basis for subsequent adjudication of the private rights involved, whether to all or any part of the lands in controversy. In the particular locality under discussion, settlement of the litigation resulting from the strife of the several boundary disputes was suspended by the local Court until the plats of the resurvey became available.

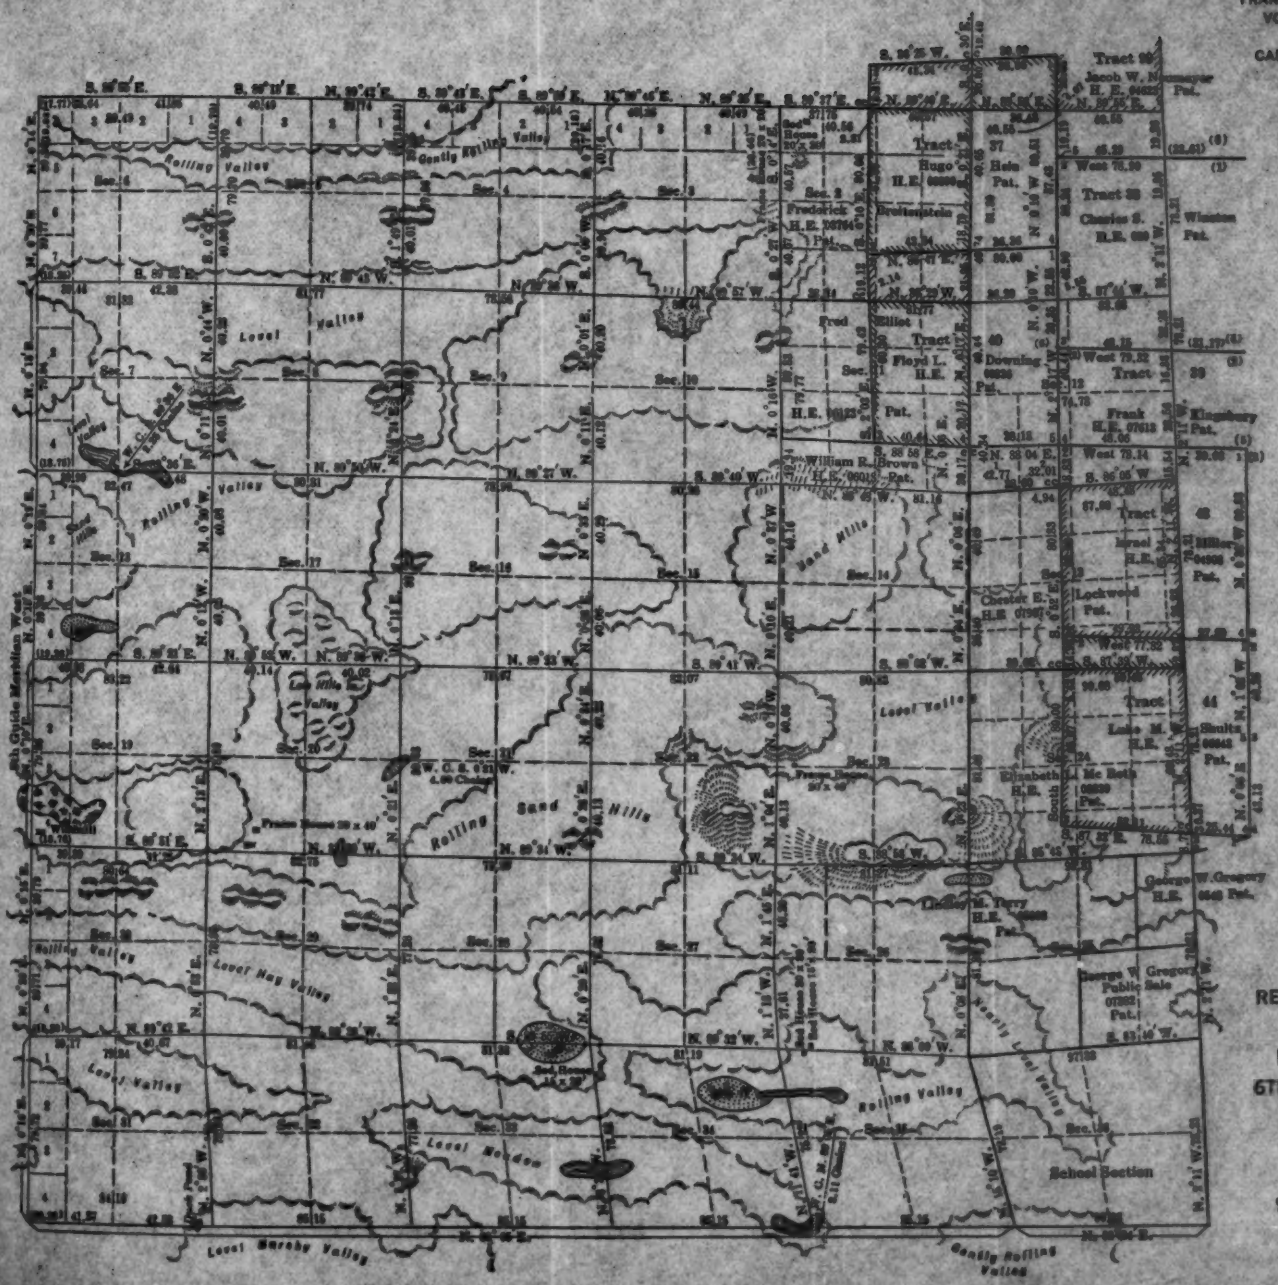
JURISDICTION

The extent of the jurisdiction and authority of the Cadastral Engineering Service through the Commissioner of the General Land Office should be clearly understood. Section 453 of the Revised Statutes, reads, in part, as follows:

"The Commissioner of the General Land Office shall perform, under the direction of the Secretary of the Interior, all executive duties appertaining to the surveying and sale of the public lands of the United States, or in any wise respecting such public lands; and, also, such as relate to private claims of lands, and the issuing of patents for all grants of lands under the authority of the Government."

The Act approved March 3d, 1899 (30 Stat., 1097), re-affirms:



"That hereafter all standard, meander, township, and section lines of the public land surveys shall, as heretofore, be established under the direction and supervision of the Commissioner of the General Land Office, whether the lands to be surveyed are within or without reservations, * * *."

The Acts of March 3d, 1909 (35 Stat., 845), and of September 21st, 1918 (40 Stat., 965), provide in part:

"That no such resurvey or retracement shall be so executed as to impair the *bona-fide* rights or claims of any claimant, entryman, or owner of lands affected by such resurvey or retracement."

From this it is clear that, in the exercise of his authority, the Commissioner of the General Land Office shall cause all resurveys to be executed in such a manner as to afford a fair and equitable identification of the original boundaries of all private claims, so that rights acquired in good faith shall be unimpaired. If title has not finally passed from the Government, the Commissioner is clothed with the authority to perform any and all acts incident, appertaining to, or necessary for, the disposal of the lands. Where a patent has been issued,

PLATE V.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXXV, No. 1469.
FARNSWORTH ON
CADASTRAL RESURVEYS.

RESURVEY OF TOWNSHIP

RANGE NO. 40 WEST
6TH PRINCIPAL MERIDIAN,
NEBRASKA

the jurisdiction of the Land Department over the lands patented terminates, and its power to examine and decide on claims to such lands becomes exhausted. *Bona-fide* rights, however, can be affected by a resurvey only in the matter of position or location on the earth's surface, and the cadastral engineer is concerned only with the question as to whether lands covered by such rights have actually been located in good faith. Other questions of good faith, such as priority of occupation, possession, continuous residence, value of improvements, and cultivation, when considered apart from the question of the position of the original survey, do not affect in any manner the problem of resurvey.

The Commissioner of the General Land Office is well qualified, and is authorized, to identify and indicate the original positions of all lands, as described in outstanding patents, and to delineate the boundaries of the public lands remaining, irrespective of whether the lands thus identified are actually occupied by a patentee or his successor in interest. However, in case of either patented or unpatented lands, where an owner or entryman seeks to maintain a claim that his rights as to location have been impaired by a resurvey, he will submit a proper protest, and the case will still remain within the jurisdiction of the General Land Office (subject, however, to the right of appeal to the Secretary of the Interior), which office after a proper consideration of the protest will reach a final adjudication of the dispute.

It will thus be realized that, by virtue of the legislation now existing, in any and all areas where uncertainties of the true locations of lands obtain, especially in those regions ridden with boundary disputes, strife, and litigation, the application of the modern resurvey procedure and the subsequent filing of a competent plat, will provide a necessary and enduring basis, not only for a comprehensive adjudication of the private rights involved, but also for the disposal of any public lands which may be found therein.

DISCUSSION

E. M. DOUGLAS,* M. AM. SOC. C. E. (by letter).—It is to be regretted that the author did not include in his paper a description in greater detail of the latest methods of making original cadastral surveys as well as resurveys. The writer's experience leads him to believe that all survey work by the General Land Office since the contract system was discontinued, has been well done by methods which may be accepted as models for other surveyors.

The writer is particularly interested in the references to the methods for determining true azimuth. The desirability of reporting true bearings should be impressed on every engineer who has long lines to run for cadastral surveys, boundaries, railroads, highways, or for public works of any kind. Too many of such surveys have been based on magnetic bearings, with no clue to the amount of the local variation of the needle, an oversight which produces much confusion and uncertainty when retracements are required. If engineers could be made to realize how easy it is to determine true azimuth by observations on the sun or on Polaris, more of them would use such methods. In reasonably clear weather, Polaris can be seen at any hour of the day with a good transit telescope.

To find Polaris in broad daylight, three things are essential:

1.—The telescope must be accurately focused. The proper focus can be found by observing the star at night and marking the telescope draw tube for future reference.

2.—The star's apparent altitude must be known within about 5 min. of arc, which can be found from tables. The U. S. Geological Survey will send such a table free, on request.

3.—The true bearing of Polaris at the time of observation must be known within less than half a degree.

The angular distance of Polaris from the true pole for any hour angle may be found from tables published by the U. S. Geological Survey, and the approximate direction of true north may be computed from a previous determination of azimuth or obtained by a magnetic needle, proper allowance being made for declination.

With the telescope properly focused, set off the computed altitude of the star on the vertical arc and turn the telescope to its estimated bearing. If the star is not seen at once, turning the telescope to the right or left a fraction of a degree without changing the altitude angle will usually bring it into view if the weather is favorable.

For general use the method described by the author for observations on the sun may be simplified somewhat without appreciable loss in accuracy.

In railroad or highway surveys, it is not necessary to observe the sun directly through a colored glass, nor is any prism or other special attachment required, but the sun's image focused on a piece of paper held 2 or 3 in. from the eyepiece of the transit, can be bisected with an error of less than 1 min. of arc. The image of cross-wires shows up plainly when the telescope is in focus.

* Topographic Engr., U. S. Geological Survey, Washington, D. C.

When observations on the sun are made rapidly, the mean of the times and of the angles measured can be used for the computation. The time may be 1 or 2 min. in error without appreciably affecting the results.

Observations on Polaris for azimuth are somewhat more accurate than those taken on the sun, but if they cannot be taken during the day, it is better to use the sun.

D. E. HUGHES,* M. AM. SOC. C. E. (by letter).—This paper is an instructive exhibit of the survey methods of the General Land Office, but the methods are not all as scientific as the title implies. On page 545, it is stated that all the temporary corners on a trial meander are moved in the same direction and through distances proportional to their distances from the point of beginning, measured along the meander lines. That statement approximates the probable truth, only as the meander approximates a straight line.

The author assumes that the method is similar to that discussed by Leonard S. Smith, M. Am. Soc. C. E., in 1912,† which is logical, although long, and gives a different result in that the temporary corners are not moved along parallel lines, nor through distances proportioned by the Land Office rule, as given by the author.

A generation ago, a similar problem was presented in *Engineering News* and some other paper simultaneously, and the Profession was surprised to find that few of the many replies were correct. Nearly all followed the rule exhibited by the author, or calculated as is done in balancing a closed traverse. A few used the same method as Mr. Smith, but the prize winner attained the same results by a shorter course, showing that all the temporary corners are to be moved in directions making constant angles with straight lines or diagonals drawn from the point of beginning to them, and through distances proportional to the lengths of those diagonals.

The reasoning, as remembered, was that, in the absence of evidence to the contrary, the field work in both surveys had to be assumed as correct in determinations of deflections and applications of chains, and, therefore, the discrepancy between the point attained by the trial lines and the existing original corner is to be attributed entirely to a difference in orientation, a difference in chain lengths, or a combination of both.

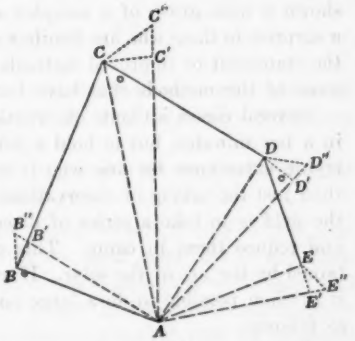

FIG. 13.

Suppose the surveyor assumes a meridian and begins at a known point, *A*, Fig. 13. Following the recorded courses and distances, he runs his trial line through *B*, *C*, *D*, to *E*, near which he finds the original corner, *E''*, and notes its course and distance according to his own survey, from *E*. He then deter-

* Los Angeles, Cal.

† *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 429.

mines by observation, calculation, or plotting, the directions and distances of E and E'' from A, according to his own survey.

If E is not on Line $A\ E''$, his survey must be revolved about A until it is, the rotation being the angle, $E\ A\ E''$. By that process, B, C, D, and E traverse arcs to B', C', D', and E'. The arcs being of equal angular measure, their chords, BB', CC', etc., are proportioned to the radii, AB, AC, etc., and make equal angles with them.

If the point, E', after revolving, is not coincident with E'', his chaining must be altered until it does coincide, the factor to be applied being the ratio of AE'' to AE. By that process, in which all lines are lengthened, or shortened as the case may be, B', C', D', and E' traverse Lines $B'\ B''$, $C'\ C''$, etc., to B'', C'', D'', and E'', these lines being proportional to the radii which they alter.

It has now been observed that, in the triangles, $B\ B'\ B''$, $C\ C'\ C''$, etc., the angles at B', C', etc., are equal, and that the adjacent sides are proportional, each side being to the corresponding side of another as are the radii or diagonals from A to them. The triangles, therefore, are similar. Hence, Lines $B\ B''$, $C\ C''$, etc., along which the temporary corners are to be moved to accomplish the required change in orientation and chain length in one operation, are themselves proportional to the diagonals from A and make equal angles with them.

If the author's rule was applied, the temporary corners would be moved to the points marked by small circles, thus requiring that some lines be revolved to the left and others to the right, and that some be lengthened and the remainder shortened. It hardly seems possible that such erratic procedure, if clearly explained, would be sanctioned by any Court.

W. J. Lightfoot,* Assoc. M. Am. Soc. C. E. (by letter).—The author has shown a wide grasp of a complex subject, and his masterly treatment is not a surprise to those who are familiar with his professional work. Supplementing the statement of improved methods used by cadastral engineers in field work, some of the methods that have been used by the writer may be of interest.

Several direct altitude observations on the sun for azimuth may be taken in a few minutes, but to hold a field party while they are being reduced is a trying experience for one who is endeavoring to accomplish something more than just the taking of observations. One method used to avoid reductions in the field is to take a series of direct observations on the sun each afternoon and reduce them in camp. This makes a reliable check on the results obtained by the use of the solar. If an observation must be reduced in the field, it is often possible to do a large part of the calculation before leaving camp, as follows:

The time and place of starting work is generally known, and the latitude of the place and declination of the sun may be obtained, therefore, in the formula,

$$\cos A = \frac{\sin \delta}{\cos \phi \cos h} - \tan \phi \tan h$$

* U. S. Cadastral Engr., Washington, D. C.

the logarithmic functions can be arranged for the entire reduction, except the cos h and tan h, which may be done quickly in the field after taking the observation.

A plat of the lines to be surveyed on a certain day may be prepared, showing each minute of latitude with its log cos and log tan, as well as a table of the declinations of the sun for each hour with log sin. When the data are arranged in this manner, it is easy to interpolate for a fractional part of a mile or for a fractional part of an hour. After an observation is taken, the only additional reference to the tables is for cos h and tan h.

For all practical purposes, it may be assumed that the ratio of the differences of the vertical angles to the differences of the horizontal angles is constant for one set of observations when the time elapsing between the taking of the first and the last observation is only a few minutes. When several observations are taken, before selecting those to be reduced, find the differences in vertical angles and the differences in horizontal angles. Then, to obtain the ratio, divide one by the other and select those for reduction that agree to the second or third decimal place. In this way, an erroneous observation may be eliminated and not used to vitiate the entire set, as is the case when the mean of a set is used in the reduction.

When the sun, moon, planet, or star is due east or west of the observer, it is said to be on the prime vertical. The altitude and hour angle may be obtained by the following formula:

Let

P = hour-angle.
ϕ = latitude.
δ = declination.
H = altitude.

Then,

$$\cos P = \cos \phi \tan \delta \text{ and } \sin H = \frac{\sin \delta}{\sin \phi}$$

The sun comes to prime vertical in northern latitudes only when its declination is north; therefore, the method can be used for solar observations only for a part of each year.

With accurate local mean time, it would be possible to use a tabulation of the azimuth of the sun made for each 10 or 15 min. of time.

CLAY TALLMAN,* ESQ. (by letter).—The purely technical side of this subject is not in the writer's line; however, during the eight years that he was Commissioner of the General Land Office, he gave much attention to its legal and practical aspects, from the standpoint of results and Governmental policy. As shown by the author, it was largely during this period that the practical experience of previous years became crystallized into settled and established principles and practice. The correct position of the "line fence" has always been a prolific source of controversy and litigation. When it is considered that, as a result of error, obliteration, or fraud, a condition of uncertainty as to property lines often affects large areas, frequently of great value, and,

* Denver, Colo.

further, that in the public land States the survey lines usually constitute the boundaries of political sub-divisions, the necessity and importance of reducing the re-establishment of lines and corners to a scientific system, legal and practical in its operation, becomes at once apparent; this, the General Land Office has worked out, not in theory only, but as applied to literally thousands of actual cases in the field, presenting every conceivable complication. It should not be concluded, however, from this that any engineer with a good general training and a "Manual" is competent to execute acceptable re-surveys; probably in no branch of engineering work are practical experience and good judgment more necessary.

The writer has no criticism to offer of the paper other than to point out that the chart (Fig. 1), on page 520, and the text relating thereto, rather overstates the importance and position of the Division of Surveys, as compared with the field organization, the two branches being co-ordinate under the Commissioner. He would like, however, to emphasize one aspect of the subject not generally appreciated, namely, that in official Government land surveys there exists a unique combination of legal and engineering functions hardly ever found in connection with any other engineering activity. If correctly and legally made and approved, an official survey fixes and determines legal rights; otherwise, the operation fails of its purpose. The first essential of such a survey is lawful authority. The order and instructions for such a survey must emanate from the proper source; the work must be performed pursuant to law by officers qualified legally as well as professionally; and the completed work likewise must receive the approval of the proper officers of the Government. The legal and engineering features are thus inter-related and inter-dependent; one without the other renders the survey ineffective, being in the contemplation of the law no survey. When it comes to re-surveys, this matter of legality of action taken and methods pursued becomes doubly important, because of the inherent complications and because the work must stand the scrutiny of the Department and, in litigated cases, of the Courts. It follows that the closest correlation of the legal and engineering branches of the work is necessary for practical operations; this is accomplished, and has been for more than a century, through the field and office organizations of the General Land Office, pursuant to the laws of Congress.

The consideration of the legal aspect of official surveys suggests a further observation deemed to be pertinent at this time. Much is being said about the re-organization of Government departments and bureaus, with a view to avoiding duplication and correlating activities; among other things, it is urged in certain quarters, that all surveying and map-making activities of the Government be consolidated in a single bureau, and to this end, it is proposed to separate the land-surveying branch from the General Land Office and place it in the proposed "engineering" bureau. From the foregoing, it is apparent that such a course would result in the destruction of a perfectly logical and necessary correlation of activities, in order to create one in name only. Although analysis of other factors affecting the matter, such as the primary purpose of land surveys as distinguished from other surveys, the

percentage of the completion of the land surveys of the country as compared with others, the bearing and importance of the records of all former surveys, and economy and efficiency of operation, furnishes ample reasons why the proposed change should be regarded unfavorably, an adequate conception of the fundamental character of official land surveys, such as the writer has endeavored to point out, should in itself be sufficient. Whatever justification there may be for a re-allocation of other Government activities, the entire matter of land surveys should remain a part of the General Land Office, where it has always been and where it belongs. The only material change in the existing plan of organization requiring action by Congress, which, in the writer's opinion, would be conducive to efficiency and economy in land-surveying operations, would be (*a*) to abolish the offices of Surveyors General and consolidate the work of those offices in the General Land Office at Washington; and (*b*) to provide for one Supervisor of Surveys who, under the direction of the Commissioner of the General Land Office, would have entire supervision of all land-surveying activities, both in the Washington office and in the field.

S. V. PROUDFIT,* ESQ. (by letter).—The writer will discuss this paper from the viewpoint of the public land lawyer, who is interested primarily in the fact of surveys rather than in the means of their accomplishment. This is especially true in the present instance, because of the broad treatment of the subject by the author, in which the limitations imposed by applied science and the law of the land are equally recognized.

The assignment of a definite description by which the locus of a tract may be accurately known is an essential prerequisite to its disposition by the United States; but, until 1910, no means to this end had been devised, either by the Legislative or Executive Branches of the Government, better than the contract system, under which the lowest bidder undertook the survey of a specific area in accordance with instructions he might receive from the Commissioner of the General Land Office. As far as any development of high engineering talent in the Department is concerned, none could have been looked for under the old contract system, and practically none resulted. The employment of the best skill possible in charge of the surveying unit in the General Land Office could not reach beyond matters of organization, for the execution of the work ultimately went to the successful bidder for the contract, whose first interest was in the quantity of his work rather than in its quality. The accuracy of the work performed under such conditions, subjected to all the tests that could be used under the ever-increasing demand for public lands, was, at the best, not susceptible of a reasonable demonstration. This is not to say that the public land surveys during that period were not usually well made, only that they were not as well made as they would have been in the hands of a National body of engineers.

The adoption of the direct system at once provided a permanent foundation for the assemblage of a body of trained cadastral engineers, to whom could be entrusted the duty of executing the public surveys with the cer-

* Member, Board of Law Review, Washington, D. C.

tainty that the latest methods of engineering science would be at the command of the Government. If difficulty had been experienced in securing satisfactory original surveys under the old system, it goes without saying that such difficulties were many times magnified when serious problems of re-survey were encountered. The necessity of protecting vested rights, as well as possible equities, in the work of restoration or substitution, called for the exercise of field control that was practically out of the question under the contract system; therefore, while it prevailed, legislation authorizing resurveys was limited, in effect, to cases where the interests of the Government were dominant. With the installation of the direct system of surveys, however, and the effective demonstration that the public service from thenceforward offered a new field to the trained surveyor, the value of such a body of Government experts received recognition at the hands of Congress in the Act of September 21st, 1918 (40 Stat. 965).

Under prior legislation, resurveys, for the most part, were only made in order properly to mark the boundaries of the public lands remaining undisposed of; but this Act is for the express purpose of furnishing a competent means for the re-establishment of boundaries of land the title to which had passed from the United States.

The first fruits, then, of the direct system of surveys was certainty in result, at less cost to the Government in the matter of original surveys, while the later result was the recognition of a disinterested scientific body of engineers to whom could be referred boundary disputes, by the Courts or individual land owners, and thus reduce to the minimum the consequences of unskillful or reckless field work that had received approval under the old system.

With the adoption of the present system of surveys, it became apparent that a new "Manual of Surveys" should be provided for the Service, and to this end a special committee organized in the Surveying Service of the General Land Office, made a careful study of the situation, its necessities as then existing, and the requisite provision for its future development. Practically, however, the relation of the "Manual" to the public surveys, the working instructions of the Commissioner of the General Land Office, who is charged with all executive duties appertaining to the survey of the public lands, is the same under the new system as under the old, and during the earlier period of transition, changes in procedure were covered by special instructions, and it was not until June 16th, 1919, that the first chapters of the new "Manual" were issued.

This apparent delay in the issuance of this new "Manual", aside from giving the new system an opportunity to develop special needs peculiar to itself, was also due to pending legislation with respect to resurveys, which finally took form in the Act of 1918.

Although all the features of the new "Manual" were given careful consideration from every viewpoint, technical, legal, and practical, when Chapter 6 was taken up, the new field of operations contemplated by the Act of 1918 called for special care in its preparation, and the final review of its provisions prior to adoption will long remain a memorable occasion to the participants in the discussion. With the Commissioner of the General Land Office presiding,

an officer familiar with the public land laws from every angle, the special committee of cadastral engineers, and three members of the Board of Law Review, each with not less than twenty-five years' experience in the adjudication of Federal land questions, the tentative contents of the chapter were considered and discussed line by line through repeated sessions of many hours' duration, with the intent that not only should the public service receive the benefit of the last word in the science of land surveys, but that the vested interests and equities of land owners should be duly protected under the law as construed by the Courts of last resort.

It is a curious comment on the story of public lands and their disposal, that it was not until the greater part of them had been surveyed, and passed out of Federal ownership, that provision was made by which the officer charged with their survey was really so equipped with statutory authority as to insure accuracy in the work. This page, however, of the story is beyond recall, and well it is, for the protection of those who have taken title under the old system, that the protection of their boundaries is not left to the tender mercies of the contractor.

H. B. PATTEN,* M. AM. SOC. C. E. (by letter).—The resurvey of the public lands of the United States presents an interesting development. It is fortunate that the author has seen fit to call the attention of the Engineering Profession at large to the results of the evolution exhibited in the work of the cadastral engineer engaged in the resurveys.

As in all other branches of science, that of cadastral engineering, when applied to resurveys, has been a gradual and extended development. The first efforts appear to be crude in light of present-day practice. A great advance was made in the public survey when the Government changed from the contract system to the direct method of executing the work. The wisdom of the change has been fully justified in the results obtained in a period of more than eleven years. One of the advantages was in providing the opportunity for more deliberate effort in field work, notwithstanding the increased expense.

It may be of interest to the Profession to call attention to the general progress of resurveys in Wyoming. Among the earliest attempts at resurveys were those authorized in 1891, under Contract 238, in the Valley of the North Platte River in what is now Converse County. Some of the cardinal principles of the resurvey were overlooked at that time, and the work led to so much confusion that it was discontinued. Recently, these lands have been resurveyed, however, in conformity with the most up-to-date practice.

Later, in 1899, resurveys were again undertaken in Wyoming of lands along Fontenelle Creek, in Lincoln County. This work conformed to the essential principles necessary for the preservation of the rights of the settlers, and fairly acceptable results were obtained.

Owing to the great extent of inexcusable error and fraud in the original surveys of the early Eighties, Congress by Act approved May 29th, 1908, authorized the resurvey of 371 townships, nearly 7 800 000 acres of land, in

* Gen. Land Office, Washington, D. C.

various parts of the State. Thus far, only a part of this work has been accomplished.

It has been suggested at times that topographic features should be determined in connection with cadastral surveys and that only one party in the field should be charged with the execution of all this work at the same time; but the fact that the requirements of the two types of surveys vary in many particulars seems to be overlooked by some, so that to carry both systems at the same time clearly increases the expense and delays the ultimate accomplishment.

A radical difference which is not always appreciated, exists between the field and office work necessary to depict the physical characteristics of the country and the intricate work involved in the proper establishment of the division and subdivision lines of the public survey called for in the rectangular system, especially in the re-establishment, restoration, and fixation of section and property lines dependent on the former position of lost or obliterated corners.

In the latter case, there is desired the correct location of the legal position of the section corners and lines as a basis for the proper adjudication of conflicting claims.

J. F. Le Baron,* M. Am. Soc. C. E. (by letter).—It is refreshing to know, even at this late date, that the surveys of the public lands are now being made by real surveyors, and are really made and not "fudged", or scamped. Every one, particularly the people in the West, know the shameful history of these surveys.

The basic plan of the surveys was conceived in wisdom and sound technique, but the method of administration was a disgrace to the nation, and has resulted in untold confusion and needless litigation and has foisted on an unsuspecting and innocent public about 6 000 000 homesteads with insecure and faulty titles, and, too often, no titles whatever, owing to erroneous delineation of boundaries and, consequently, erroneous areas of the sections and subdivisions into which the land was divided.

This era of mal-administration is past, and the members of the Engineering Profession can obtain some comfort from the thought that, by devoting themselves to the rectification of these errors, they can do much to assist the unfortunate victims of a pernicious system.

About forty years ago, while building a railroad in Florida, the writer was in a locality where land had rapidly appreciated in value, and where the public land surveys, which had been made about thirty or forty years before, were in the usual condition of uncertainty and inaccuracy. The writer spent some of his spare time to trying to re-locate last corners and to decide the location of many disputed lines between valuable orange groves. He was appointed a U. S. Deputy and also U. S. Mineral Surveyor to survey some military reservations and phosphate mining claims.

Later, he removed to Jacksonville, Fla., and was engaged to establish the lines of the five old Spanish grants on which that city is built. About 50%

* Cons. Engr., Essex, Mass.

of these grants, at that time, were covered with commercial and residential buildings. The corners of all these grants had long ago been destroyed by the growth of the city, but all the land titles in the city were based on these grant lines and corners. It was no easy task, but after nearly a year's work, they were re-located satisfactorily.

In recovering several of the old corners outside of the compactly built up city (Jacksonville), the tap-roots of the hard pine witness trees were found. The writer has often found old well blazed section lines leading to a point 20 to 75 ft. from the established corner, which corner might be also identified by other blazed lines leading to it from other directions and by well marked and identified witness trees. Generally speaking, the distances from the corner to the witness trees were not measured, but were either paced or estimated, although the courses given in the original field notes were generally correct. Lengths of section lines generally overrun 10 to 30 links, making the areas of the sections larger than the acreage given on the official plats. It would be interesting to know how many acres of land the Government has lost by this error in the whole of the public lands. It is safe to say it would be up in the millions of acres.

The fraudulent surveying of shore lines of rivers and other bodies of water has worked serious harm. Intending settlers or purchasers, deceived by the officially certified plats furnished by the Government, have selected lands, paid for them, and often settled on them, only to discover the shore line mislocated and possibly a bay or other body of water where the Government plats showed high land, and their acreage thus reduced, oftentimes, from 10 to 20 acres.

In 1876, the surveys had been completed in ten States and Territories, and were in progress in twenty others. They are now practically completed, except in Alaska and Utah, and resurveys in some States. Omitting Alaska, the arable acreage of which is unknown, there remains 19 000 000 acres to be surveyed in Utah.

HOWARD RICHARDS FARNSWORTH,* ASSOC. M. AM. SOC. C. E. (by letter).—The character of the subject chosen, together with the definite intention on the part of the writer to present to the Profession a résumé of those principles which official experience has proven will, when properly applied, assist the engineer in the solution of any problem of resurvey encountered, whatever the degree of complexity, has precluded any departure into the field of original Government surveys.

It may be stated, however, that the instrumental equipment and the field methods used for the projection and measurement of lines of both surveys and resurveys are much the same, but the problems encountered in the former, although difficult, are usually of a distinctly different nature—the element of private interest and vested rights not having such primary bearing. This reference, of course, does not include those original surveys executed of lands sometimes found along meanderable bodies of water, of islands, fictitious lakes, or other tracts, which it develops were erroneously omitted from the original

* U. S. Cadastral Engr., Gen. Land Office, Div. of Surveys, Washington, D. C.

township survey, nor does it include those other surveys, which the General Land Office alone is authorized and qualified under the law to execute, required for the identification of lands for purposes of evidence in suits or proceedings in behalf of the United States. This class of fragmentary work involves questions of status and classification as to survey and, thus, becomes closely allied to resurveys, inasmuch as the private rights involved are generally of paramount importance. The investigations and surveys which are now being executed in the bed and flood-plain of the Red River in connection with the Oklahoma-Texas boundary litigation, form an example of work of this class.

Mr. Douglas properly emphasizes the value of a correct reference of the basic system of the lines of any public works to the true meridian, as incidental to a finished return. In any long traverse such as a railroad, canal, or highway survey, where there is often no opportunity for closure, correct bearings of lines are especially desirable. In such cases, the reported definite relation of each line to the meridian will provide the means by which to identify each line of the survey although only one point of the whole system may be known.

Attention has been called by Mr. Douglas to the ease with which the necessary co-ordinates of Polaris may be found in tabular form, for use in the identification of the star during the daylight hours. It might also be well to recall that precise tables of this character may be found in the "Nautical Almanac" published by the Naval Observatory.

A similar tabulation also appears in the 1921 edition of the "Ephemeris of the Sun and Polaris," to which pamphlet frequent reference was made by the writer in his paper. This table was formulated by the General Land Office to facilitate the determination of the latitude by an altitude observation of Polaris at any hour angle, the latitude of the station being determined by applying a primary and supplemental correction to the observed altitude of Polaris, properly corrected for refraction. The tabulation is concise and practical in its operation and the vertical angular values of Polaris above or below the pole for any mean time hour angle are readily taken from it. From a station of known latitude, the position in altitude of Polaris is thus easily determined. The position in azimuth of Polaris for a known latitude and a stated mean time hour angle and declination is readily apparent by reference to the table of azimuths of Polaris also to be found in this "Ephemeris". By the use of these two tables, the position of Polaris is easily found for any hour angle and latitude, from any station within the United States.

Mr. Hughes exhibits much assurance in the revival of an old subject. The exposition of his method of traverse adjustment is made to the exclusion of all others, and it is championed with the courage of true conviction.

The earliest presentation of this "twist" method as far as the writer knows was made by Mr. F. Hodgeman,* in 1895. Mr. Hodgeman, however, guards the method properly by restricting its application to cases where it might definitely be known that the angular measurement and rhumb-line projections were perfectly accomplished and, therefore, that the whole error might

* "Manual of Land Surveying", pp. 78–81.

theoretically be charged to defective measurement and the initial meridian determination. He explains,* however, that in practice numerous additional errors occur from many causes and he then reiterates the first fundamental principle of balancing, a rule which has not ceased to be as sound in logic as it is unassailable, as follows:

"As the sum of the lengths of all the courses is to the length of each course, so is the total error to the error of that course."

The method of traverse adjustment so vigorously championed by Mr. Hughes was known, discussed, and its limitations fully recognized many years ago by the Cadastral Engineering Service and has since been considered to be inapplicable to the reproduction of meander lines. In all other cases where this "twist" method has been brought to the writer's attention, its advocates have claimed for it only the limited application possible under a positive assumption as to the specific manner in which the errors in the survey were made, rather than the negation appearing in the expression, "in the absence of evidence to the contrary". As Mr. Hughes makes no attempt to confirm this negation, it follows that if there is no evidence in opposition to the specific assumption then there is also, by implication, certainly none in its favor, and the amazing conclusion is then reached that, in the absence of any knowledge whatever as to the contributory causes, all the error for this reason must be definitely assigned to the performance of certain functions and excluded from others.

According to the most elementary conception of the law of probability, if a lack of knowledge or evidence is admitted as to certain causes (the functions performed by instrument and chain), all elements contained therein must share responsibility in the known, combined effect (the closing error found). In the absence, therefore, of definite knowledge to the contrary, both instrument and chain in performing all their functions must be held to be mutually responsible for errors found, since each, independent of the other, measures one of the two polar co-ordinates necessary for the fixation of a definite point on the earth's surface. The combined effect of the instrumental errors in azimuth, angular deflection, and adjustment, are chargeable with the same degree of inaccuracy as the combined effect of chain errors in leveling (or reduction to horizontal by clinometer), in the alignment by chainmen, and unit errors in the length of chain.

It should not be necessary to recall the fundamental principle that, when two or more independent measuring functions are performed to determine the co-ordinates of a point, the degree of accuracy with which that point is fixed substantially depends on the accuracy obtained by the least accurate of the various functions entering into the process. To perform the linear measurement in a definitely and materially less accurate manner than the angular measurement and projection of lines, would involve a loose and rash expenditure of time in the accomplishment of an accuracy which serves no purpose. A surveyor will avoid any ineffective refinements and, unconsciously, will regulate the operation of instrument and chain so that if either has a limit of accuracy materially different from the other, a needless waste of time will

* "Manual of Land Surveying", pp. 120–121.

be avoided by no attempt at refinements materially inside the limits of the least accurate. This is certainly true as to the later survey or the resurvey which develops the error and, without doubt, is also true of the original survey. Naturally, then, a bold assumption as to the specific cause of error, that the discrepancy between the results of the original survey and the resurvey can "be attributed entirely to a difference in orientation, a difference in chain lengths, or a combination of both," and that, therefore, the error found was due entirely to erroneous orientation and chain lengths in both surveys, is particularly baseless and untenable.

Although it is recognized that the mechanical errors in chaining are compensative and subject to one law and that the unit errors in chain length and errors in alignment are cumulative and subject to a different law, the only permissible hypothesis as to the combined error of both chain and instrument is, that this combined error, which in its combined effect represents the result of all contributory causes, varies directly with the length of the line surveyed. When this conclusion is reached, the method of restoration follows as a matter of mathematical certainty and is that given in the paper. Any other hypothesis makes necessary an assumption of a definite knowledge as to the particular contributory causes which were previously held to be unknown. The question, then, is primarily one of hypothesis, for the proper method will follow as a secondary matter of accomplishment. For instance, in those cases where it is definitely known that the original surveyor inadvertently has confined all the error to the measurement and the initial azimuth, or perhaps, with a view to the ultimate application of this "twist" plan of restoration, has purposely done so, then, without doubt, the method set forth by Mr. Hughes follows with equal certainty.

In the case of a meander line, the angle-points of the traverse are established without monuments, except at the initial and terminal points, and the known error is that which results from the extension of the record bearings and lengths by a later and presumably more accurate survey from either existing terminal monument toward the other, or from both toward the particular angle-point to be recovered (see Figs. 9 and 10). The direction and extent of the error thus developed is the same for all points along the traverse; that is, it must be considered from the record of a single later survey, regardless of its order of recorded progress, that it was extended from either existing terminal monument toward the other or from both toward any one of the angle-points, on the original record bearings and lengths; in which case, the error developed will be the same for all points.

Considering any one of the angle-points for the purpose of illustration, the recovery of its original position by a later survey must depend on and be influenced by all the existing evidence of such original position. The sum total of all this evidence is the two existing terminal monuments and the record of the original survey as to the courses and distances therefrom. The only logical manner whereby the influence of the known evidence can be properly exerted on the ultimate recovery of the point in question, is by extending from each existing monument the original record courses and

distances until the angle-point is reached where, unless no error is developed, two separate points for the position thereof will be found (referred to hereinafter as temporary points, see Fig. 9). If only one original terminal monument is assumed to be known, then the position reached for the angle-point from this monument should be adopted at once as the ultimate position thereof. Similarly, if the other of the terminal monuments is known, and the first one is lost, then the other of the two temporary points would be adopted with equal assurance as the final position. However, in the presence of both terminal monuments and two separate temporary points, the true position for the restored angle-point must be such that it will be nearest to both the temporary points indicated by the terminal monuments, or somewhere on a straight line between them. If the errors vary directly with the length of the line measured, this restored point will occupy such a position on this straight line, that it will divide the line into distances which are proportional to the length of the lines measured from each terminal monument.

By presenting the problem in this manner, the careful reader must see at once that each existing original monument and all the calls of the original record therefrom have been made to exert their proper influence in the recovery of the required angle-point, and he will realize that not only all legal requirements are fulfilled thereby, but the scientific requirements as well. The theory of non-concurrent parallel forces might be applied to this problem, or the principles involved in a determination of the "center of gravity", but the same resultant point would be reached. No one element whether it is the known monuments, the bearings, or the distances, can be regarded as evidence less competent than any other and to neglect any one of them arbitrarily and without reason, would be indefensible.

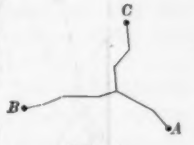

FIG. 14.

Consider, now, that, in the original record, a third existing corner monument had been connected by a traverse line to any one of the angle-points of the first traverse line, as shown in Fig. 14.

It would be interesting if Mr. Hughes would apply his method to the restoration of the angle-point common to both traverse lines. If each of the three existing corners was to share in the control of the restored angle-point, he would have no option, but to apply his method to the three pairs of corners separately, that is, first between Monuments *A* and *B*, second between Monuments *A* and *C*, and, third, between Monuments *B* and *C*. In this event, three different positions for the restored angle-point would result, and he could not escape the necessity for consideration of a mean position of the three for his final position. A logical extension of this plan of restoration would also give two separate positions for every angle-point, other than the common point just referred to, in the tri-system. By determining a mean position for all such points and connecting them with right lines, what then would become of the proportional lengths of lines and the constant angle of twist?

In contrast with the inconsistency produced by the foregoing, the application of a method will be investigated, conceived in the assumption that all

existing corners and all the calls of the original record are to share alike in a proportioned influence on the final position of the angle-point to be recovered.

Extend the lines on the record bearings and lengths from each existing monument (*A*, *B* and *C*), to each angle-point in the tri-system. This gives at once three temporary points for each angle-point of the system. Each of these points being weighed inversely as its distance from the corresponding existing monument, the mean position is found by applying the principle of non-concurrent parallel forces as explained in the paper (see Figs. 8 and 9). The application of this method is general, no matter how many existing monuments are considered as being connected with the point, the restored position of which is required, and no matter how complicated the system of the record survey may be. The results, in all cases, are logical and consistent.

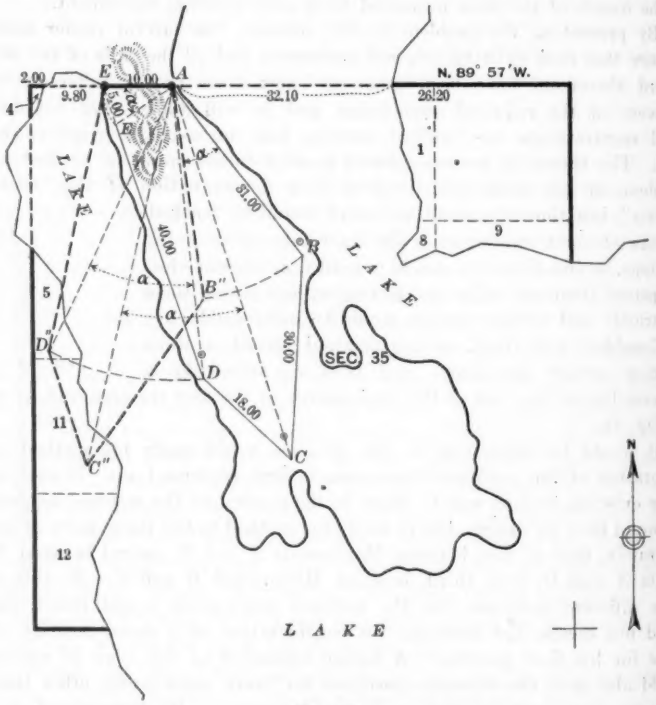

FIG. 15.

The absurdities which must be expected in any general application of the Hughes plan of restoration are only partly evident from Fig. 13. To make it more apparent, attention is invited to Fig. 15, which illustrates the restoration of the erroneous original meanders of a peninsula. This arrangement of the lines of the traverse is not unusual, and is often en-

countered also in the fixation of the boundaries of fictitious lakes. It will be observed that the assumed closing error is not excessive and may well be expected in view of the relatively long distance traversed. All the angle-points and terminal monuments have been designated in this diagram with letters corresponding to those assigned by Mr. Hughes in Fig. 13, in order that the restoration can be easily accomplished, following the plan as explained by him. A fanciful position will immediately be occupied by the traverse system after its rigid orientation in azimuth, in fact, such resultant positions will sometimes reach into entirely different quadrants. The corresponding positions occupied by the angle-points, when reproduced by the application of the only logical method, are those indicated by the small circles.

It is believed that Mr. Hughes has either not read the paper as carefully as he should or else that he has allowed his judgment to be influenced more by the apparent geometrical elegance of the method he advocates than by a proper consideration of what is to be accomplished.

Mr. Tallman furnishes conclusive evidence of the keen interest that he took in the work of the Cadastral Engineering Service throughout his incumbency as Commissioner of the General Land Office, and of his intimate knowledge of the general subject from the executive and legal point of view. As he has stated, it was largely during this period that previous experience developed into established principles and practice. He realized that, to a large extent, the adjudications of the Land Department and the operation of the various land laws must rest on and be influenced by the preliminary determinations of the cadastral engineer.

Effective safeguards for the elimination of errors in field observations, and practical suggestions for saving time in the resulting reduction operations, are frequently developed and verified through individual use. Such, apparently, is the case with Mr. Lightfoot, who has made valuable suggestions of methods he has used. Where one finds real efficiency in the expenditure of time, with a due regard for accuracy, one will also find the origin of progressive ideas, and investigations looking to the development of new forms. Mr. Lightfoot's suggestion of the possible use of a tabulation of azimuths of the sun is interesting, and the writer would like to have had him pursue the investigation of such a tabulation further, in order to determine its practicality.

There is no one who deserves more studious attention in a discussion on the fact of cadastral surveys, their foundation in law, and their legislative development than Judge Proudfit, who has given a most interesting discussion of the subjects on which he has touched. Particular attention has been given by him to the advantages immediately accruing to the Government in the abolition of the contract and the establishment of the direct method of execution. Mr. Patten and Mr. Le Baron have also stressed this point. When it is considered that the public domain is the people's most valuable heritage, it seems that the principle of conservation, as exemplified by proper facilities for accurate identification of the units of disposal, was applied to it none too soon. The Government's industrial experiences

during the World War have furnished renewed and costly examples of what the public may continue to expect in its relations with an unscrupulous contractor. "Certainty in result" in this period of enlightenment surely should continue to be the primary object. The maintenance of a National body of civil engineers within the organization of the General Land Office to administer and execute the complicated work of Federal cadastral surveys and resurveys, as so aptly referred to by Judge Proudfit, is a natural pre-requisite to the attainment of certainty in results. The writer knows of few instances involving scientific endeavor, where the Government is obtaining satisfactory results through the medium of a contractor, even in the presence of the most rigorous safeguards.

It should be stated, in this connection, that those efforts toward perfection in results that this body of engineers is consistently maintaining, have been materially aided by the confidence and constructive co-operation of the members of the Board of Law Review of the General Land Office. The Cadastral Engineering Service is fortified in the knowledge that the conclusions and material prepared by its Manual Board for the first six chapters of the new "Manual of Surveying Instructions", stood with steady permanence the searching inquiry and critical judicial consideration of three such authorities on the jurisdiction and practice of the United States Land Department as Judges Samuel V. Proudfit, John McPhaul, and William H. Lewis, who participated in the closing conferences on these chapters before official approval. The familiar tradition involving the supposed indifference of the lawyer toward the engineer, certainly did not apply in the closing conference on the "Manual", recalled by Judge Proudfit, when he and his colleagues; the Commissioner; Mr. Frank M. Johnson, Supervisor of Surveys; and the Manual Board composed of Mr. Walter T. Paine, Chairman, associated with Messrs. Arthur D. Kidder, Thomas C. Havell, William H. Craigue, and Clinton G. Tudor, reached a unanimous agreement on the material prepared and presented by the Board for final consideration. When it is recalled that this work had previously received the endorsement of Mr. Charles L. Du Bois, for twenty-five years Chief of the Division of Surveys and Resurveys, its firm foundation in science and law will be duly appreciated, commensurate with the extent and quality of all the effort expended in its production.

Mr. Patten has reviewed certain interesting events in connection with some of the resurvey projects in the State of Wyoming, and Mr. Le Baron recalls the difficulties he encountered in the recovery of the obliterated evidence of the early surveys in Florida. His experience with the restoration of the lines of the five old Spanish land grants on which the City of Jacksonville is based, is illustrative of the difficulties encountered in the restoration of the irregular boundaries of some of these old grant lands, which are now often of great value. A recent example of a similar resurvey is the reproduction by the Cadastral Engineering Service of the boundaries of a tract, known as Rancho Potrero Chico, in Ts. 1 and 2 S., R. 11 W., S. B. M., California, in the suburbs of Los Angeles. In this case, clear identification of the boundaries of the granted lands had not been provided until the filing of the resurvey plat in 1920. As clear title had never been asserted to this tract,

a United States patent covering it had still to issue on that date. The several claimants of record and parties in interest included eight individuals, the State of California, and one oil corporation. The tract was reported to be worth $1 000 per acre for agriculture and, in addition, to be covered with producing oil wells, thus making the property exceedingly valuable. Mr. Lightfoot will recall this interesting case, as he participated in the field work. The old archives of Spanish and Mexican origin, which are to be found in the files of the local offices of U. S. Surveyors General, include numerous interesting documents, many of which bear the signatures of the reigning monarchs and the rulers of those countries.

Mr. Le Baron's implication that an irrelation generally exists between the legal acreage as shown on official plats and actual conditions on the ground, and that there is always a corresponding loss of land by the Government, is somewhat misleading. As a matter of fact, it is found that the ordinary theories of probability are fully verified by the results of boundary retracements, other than those of limited scope, and that excesses and deficiencies in original measurements are developed with equal frequency. It might also be well to correct the statistical data which have been given as to the extent of completion of the subdivision of the public domain, and the present status of resurveys. The public land States include all the States, except the thirteen original States and Maine, Vermont, Kentucky, Tennessee, West Virginia, and Texas. The total land surface of the public land States is estimated at 1 442 200 320 acres, or more than three-fourths of the total area of the forty-eight States. The Territory of Alaska is estimated to cover 378 165 760 acres. On June 30th, 1921, about 168 000 000 acres of public land in the public land States had not yet been surveyed. In the Territory of Alaska, the area which has been surveyed is insignificant compared with the total area of the Territory. Retracements and resurveys have been and are now being executed in nearly all the Middle and Far Western States and in many Eastern-Southern States. As settlement and land values increase, the demand for Federal resurveys increases and often exceeds the available facilities for supply.

Land patents do not convey title primarily to a stipulated number of acres, but rather to certain designated units of disposal as fixed by the boundaries thereof. The area content is secondary and is that which is actually found to be embraced within the stated boundaries. Consequently, the writer is somewhat at a loss to understand what was intended by Mr. Le Baron in the suggestion that land patents had sometimes been issued which conveyed "no titles whatever." The nearest approach to this condition might be in a case of partial or total conflict of one claim with another, a situation which ordinarily must have been known to the affected entrymen, but had not been revealed to the General Land Office until the patents had been issued and were beyond recall. In such a case, the proprietary authority conveyed by the respective patents would be properly commensurate with the good faith of the entrymen during the progress of the entries toward the conferring of the titles, as each conflicting claimant would be fully aware of the equitable and relative rights of the other. If a just adjudication was made, neither claimant could rightfully consider himself to be injured.

The idea that patents might sometimes not convey title, even though not confronted by any adverse or superior claim, reminds one of the suggestion sometimes advanced that when the record of the original survey, in a given locality, cannot be reconciled with the relative positions of the existing corners, or that when no physical evidence whatever of original monuments can be found, the inference is justified that the original surveyor did not run the lines as he stated in his field notes and, therefore, could not have built any corners; in which event, it is then maintained that the original corners cannot be recovered in a resurvey, or restored for the control of the boundaries of alienated lands.

Such a conclusion is based on entirely false premises. Resurveys do not attempt to reproduce that which once existed and is lost, but, rather, they reproduce that which the original record purports to exist. The physical corner monument itself is, of course, the best existing evidence of the position of the original survey as described in the record; however, if all the monuments had been originally established and were afterward lost, the same problem would confront one, as in the case where they were never established. In either case, one has the positions where the original record claims they were, and, therefore, it is not vital to the restoration whether or not the physical monuments were ever actually established, since, in both cases, all physical evidence thereof has been considered to be lost. The original survey, when official, is an enduring basis for disposal, and land titles are not to be invalidated at any time through the destruction of the corners. The survey is made enduring through the filing of the official field notes and plats. The proper interpretation of this original record, as referred to local conditions, for determining questions of good faith in location, makes necessary the application of the definition of good faith, such as is given on page 551.

A claimant is not necessarily involved in litigation in the adjudication of an area in conflict (see Plate V). In general, a conflict is subject to clearance by private mutual agreement, adjudication by a competent Court, or, when either party admits and asserts no proprietary right to such an area and voluntarily relinquishes all interest in the same, then, also, by the law providing for the amendment of entries or selections and re-issuance of patents, Section 2372, R. S., as amended by the Act approved February 24th, 1909 (35 Stat., 645). On a satisfactory showing by either party and reconveyance to the Government of unencumbered title covering the original units of disposal invaded by such conflicts, a re-described entry or patent will be issued by the General Land Office, reaffirming his interest in and title to the land, exclusive of the conflict. In these cases, the claimant is then allowed to take in lieu thereof, any equivalent area of vacant available land of appropriate class, which may be contiguous, or if none is adjoining, then to complete his homestead, selection, or other right, by taking any available equivalent area of vacant land, which may not be adjoining, the latter in the form of a supplementary entry or selection under the entry laws. The particular plan adopted for the clearance of any conflict depends on the attitude assumed by the parties in interest; however, in the end, each claimant should receive that to which he is entitled.

The writer has reviewed in some detail the subject of conflicts, in the belief that the discussion will be of some value to engineers when they encounter these perplexing problems in the field. Concluding the discussion, there appears to be a general agreement that the subject of cadastral resurveys requires the most deliberate consideration by the Engineering Profession, in order that when attempts at restoration are made, the fixation of land boundaries and the delineation of private rights may be accomplished with finality.

Paper No. 1490

BUCKLING OF ELASTIC STRUCTURES

By H. M. Westergaard,* Esq.†

With Discussion by Messrs. George Paaswell, Eugene E. Halmos, Edward Godfrey, and H. M. Westergaard.

Synopsis

The buckling of a slender column under an axial load and the collapse of a thin cylinder under a uniform external pressure have long been recognized to be related structural phenomena. In both cases, the structural action may be described by the common term, buckling. If the column is perfectly straight, the load on it exactly central, and the material perfectly homogeneous and elastic, when the load is increased gradually from zero, the column remains straight until the load reaches a critical value at which the column bends out suddenly. In the same way, if the cylinder is exactly circular, the outside pressure on it absolutely uniform, and the material perfectly homogeneous and elastic, when the pressure is increased gradually from zero, the cylinder remains circular until the pressure reaches a critical value at which the cylinder deflects from the circular shape. In both cases, the deflections increase at the critical value of the load without any increase of the load. Until the deflections have become large, there is a neutral equilibrium, that is, one maintained at constant load throughout a continuous range of configurations. This neutral equilibrium is the criterion of what may be termed pure elastic buckling.

If the column is not perfectly straight, if the axial load on it is slightly eccentric, or if there are transverse loads in addition to the axial load, and, in the same way, if the cylinder is not perfectly circular and homogeneous, or the load on it not exactly uniform, then certain elements of the pure buckling may still be traced, and the structural action may still be characterized as buckling. The deflections increase slowly at first, with slowly increasing loads, but they increase rapidly as the loads approach the critical values. This type of buckling may be looked on as a mixed action lying between two extremes, one

* Asst. Prof., Theoretical and Applied Mechanics, Univ. of Illinois, Urbana, Ill.
† Now Assoc. M. Am. Soc. C. E.

of which is the pure elastic buckling first mentioned and the other the ordinary structural action in which the deformations and stresses are proportional to the loads, for example, the ordinary bending action of a beam loaded by transverse forces only.

There is, as may be seen from the Bibliography (Part VII), a rather voluminous literature on buckling. Most of the analyses made in the past deal primarily, however, with the various cases of pure buckling and leave the questions of mixed buckling on the whole unsettled. The present investigation deals primarily with the subject of mixed buckling. A general analysis is made of this type of buckling, and the results are applied to various specific cases.

The method followed, to some extent, is to present results first, and theory afterward. For example, the formulas in Parts II and III are derived from the general formulas in Parts IV and V. The subject-matter is arranged as follows:

I.—Introduction (Articles 1-2), in which certain limiting assumptions are introduced, examples of buckling are discussed, and some terms are defined.

II.—Formulas Applying to Columns Which Are Loaded by Axial and by Transverse Forces at the Same Time (Articles 3-9), in which approximate and exact formulas are given for columns with hinged or fixed ends, loaded by a distributed or by a concentrated transverse load, or by end couples.

III.—Slabs and Similar Structures (Articles 10-11), in which formulas are given for rectangular homogeneous slabs, simply supported on four sides, and for a double system of crossing beams connected at the cross-points.

IV.—General Theory of Structural Actions in Which the Stresses Are not Proportional to the Loads, Although Hooke's Law Applies in Each Element of the Structure, and Although the Deformations Are Small (Articles 12-27), in which by the principle of energy minimum some general formulas are derived, by which one may compute any structural effect, such as bending moment, stress, or deflection, in mixed buckling, provided the corresponding case of pure buckling is known.

V.—Differential Equations Applying to Some Definite Cases (Articles 28-31).

VI.—Summary (Article 32).

VII.—Classified Bibliography.

I.—Introduction

1.—Limiting Assumptions, Examples of Buckling, and Definitions of the Terms Orthostatic, Astatic, and Heterostatic.—Two assumptions are usually made in the analysis of stresses in structures, which have been shown by experience, by test, and by analysis, to be warranted within a wide range of cases, and they will be made throughout this investigation. One assumption is that at all points the unit deformations, or strains, are proportional to or are linear functions of the stresses; the other is that the elastic deflections from the original shape are small and may be considered as infin-

itesimal when compared with the main dimensions of the structure, or, in this sense, the structures are assumed to be stiff. These two assumptions, of elasticity and stiffness, limit and simplify the problem to be investigated.

When both assumptions are warranted, one may conclude in many, although not in all, cases that a stress or a deflection produced by two loads combined is the sum of the stresses or deflections produced by each of the two loads acting separately; that is, the principle of superposition is found to apply to the loads, stresses, and deflections. The general principle of superposition, when it applies, states that the effect of two or more causes combined is the sum of the effects of the separate causes; for example, the stress due to a total load consisting of live load plus dead load is computed, in accordance with this principle, by adding the live load stress to the dead load stress. An important conclusion drawn from the law of superposition of loads, stresses, and deflections is that when all the external loads are increased in a certain proportion, the stresses and the deflections are increased in the same proportion.

It is evident that the law of superposition does not apply generally to the cases of buckling which have been mentioned. In fact, one may define elastic buckling in the most general sense as a structural action in which the stresses are not, in general, proportional to the loads, although Hooke's law applies in each element of the structure, and although the displacements are small; or, as a structural action in which the assumptions of elasticity and stiffness apply, but in which the law of superposition of loads, stresses, and deflections does not apply to the structure as a whole, although it may apply to certain parts of it. It is intended to investigate elastic buckling in this sense of the term.

A special nomenclature for the two actions which have been referred to as pure buckling and mixed buckling will be introduced later. First, the nature of these actions will be explained by means of examples.

Beginning with pure buckling: The example, already referred to, of the straight slender column buckling under a central axial load, shows the most characteristic features. Let the ends be simply supported or hinged, and the cross-section be constant. Then, at the critical load, given by Euler's well-known formula, the transverse deflections which were zero or negligible at smaller loads, increase suddenly. The neutral equilibrium, maintained at this constant critical load throughout a continuous range of increasing deflections, is the criterion of pure buckling. The load may be increased beyond the critical value at which the bending ordinarily begins, and still the column may be made to remain in equilibrium in an undeflected state. This equilibrium is unstable, however; that is, it would be disturbed by a small force from the side, or by a small local eccentricity of the elastic resistances of the cross-section. At higher "critical loads", other states of neutral elastic equilibrium may be obtained, in each of which the column may buckle into a curve consisting of some definite number of half waves. All the neutral equilibria produced under the higher critical loads are unstable. When they do occur, they will tend to revert to the neutral equilibrium which was produced first, and the maximum load which can be applied, will drop to the corresponding lowest critical value. The lowest critical load at which buckling first occurs

is of particular interest, because it defines a limit of the strength, but it will also be shown, subsequently, that the study of the higher critical loads and of their corresponding neutral equilibria leads to a solution of important structural problems.

Fig. 1 illustrates some typical cases of pure buckling of elastic structures. Fig. 1 (*A*) to Fig. 1 (*F*) shows some originally straight columns with various end conditions. Column *A* has hinged ends, Column *B* fixed ends, Columns *C* and *D* have one free end, while Columns *E* and *F* have elastic supports at the ends. In the case of Column *C*, the load at the free end is assumed to remain parallel to itself while the deflections increase, while in Column *D* the load applied at the upper end of the column is inclined in proportion to the deflection of that point. If Columns *C* and *D* are of the same dimensions and material, then Column *D* will buckle at a lower load than Column *C*. In the cases of Columns *E* and *F*, the same types of buckling may occur as in the case of Column *A*, but, in addition, neutral equilibria may be produced by the deformation of the spring supports, whereby the column moves into a position which is inclined with respect to the vertical, as indicated in the diagram. Fig. 1 (*G*) shows a section of a long, thin-shell cylinder under uniform outside pressure. When the pressure reaches a critical value, the surface buckles, as indicated by the dotted line. The typical neutral equilibrium is found here also. Furthermore, a larger number of waves in the deflected surface might be formed at higher "critical pressures". Only the lowest critical load gives a stable neutral equilibrium. All the neutral equilibria which could be maintained at the higher critical pressures, are unstable; that is, the general characteristic features mentioned for a slender, straight column exist also in this case.

Fig. 1 (*H*) shows a curved compression member which carries forces at the ends and, in addition, a distributed pressure from the convex side. If the original center line is a possible line of pressure, that is, if it is a funicular curve for the side pressures, then buckling may take place, as in the case of the circular cylinder. Fig. 1 (*J*) shows a bridge of the pony-truss type; the sidewise buckling of the arch is restrained by the stiffness of the verticals, but this restraint may be overcome at a certain limiting pressure in the arch. Fig 1 (*K*) and Fig. 1 (*L*) represent slabs loaded from the ends; the case shown in Fig. 1 (*L*) occurs, for example, in the web of a plate girder under the influence of the shear. The edges may be either fixed or free to turn. At critical loads, the slabs will buckle into various surfaces. The case shown in Fig. 1 (*M*) is similar to that in Fig. 1 (*K*), only the continuous slab is replaced by a double system of crossing beams. Fig. 1 (*N*) is a hinged-end column with a continuous elastic support from the side; the springs shown in the diagram are assumed to be without stress when the column is straight. The possible curves of deflection are similar to those in Fig. 1 (*A*), but the critical loads, if the column itself is the same, are essentially higher, and the number of half waves of the deflected curve corresponding to the lowest load is likely to be two or more, depending on the stiffness of the side support. Fig. 1 (*O*) shows a cylinder under outside pressure, but with the surface stiffened by rings. The relation of this case to that of the cylinder, Fig. 1 (*G*), is similar to the relation existing between the columns, Fig. 1 (*N*) and Fig. 1 (*A*). If the two cylin-

ders are similar, Fig. 1 (*O*) will collapse at a higher load than Fig. 1 (*G*), and it is likely that a larger number of surface waves will be formed in the process of buckling. Finally, Fig. 1 (*P*) shows a truss column, which may buckle in the same way as the column shown in Fig. 1 (*A*).

Other examples may be mentioned: A long shaft or wire may buckle into a spiral shape under the influence of either torsion alone or torsion combined with an axial load. This action is most easily demonstrated by twisting a short piece of string. A high narrow beam or blade may bend out sidewise, tip, or twist, under the influence of a bending load which lies initially in the plane of maximum rigidity, that is, in the plane of symmetry containing the large dimension of the cross-section. At a certain critical value of the load, the torsional rigidity becomes insufficient, and the beam tips. This action is demonstrated when one tries to hold a long strip of paper or a T-square as a horizontal cantilever with the flat side vertical. A thin cylindrical shell or a tubular strut may buckle into a double-curved surface under the influence of a compressive load parallel to the axis. Buckling may occur in a spherical shell loaded by a uniform outside pressure. A closely related dynamical action is the whirling of a shaft, whereby the shaft bends out when a critical speed has been reached. Concerning the larger number of cases of pure buckling which have been mentioned, reference is made to the literature in the classified Bibliography (Part VII). As far as pure buckling is concerned, the present investigation deals mainly with the general aspects of this action and with its relations to mixed buckling.

The nature of mixed buckling will now be explained. Mixed buckling may occur in any structure in which pure buckling is possible; for example, with any of the structures shown in Fig. 1. A load must be acting which can be resolved into two component parts: One, a load which alone would produce stresses and deflections that are proportional to it in accordance with the principle of superposition; the other, a load which alone would produce pure buckling when increased to a critical intensity. Assume that the two loads produce deformations and stresses in the same parts of the structure. Assume also that the two components of the load act together and are gradually increased in the same proportion from small initial values. Then, a structural action will take place in which, in general, the stresses are not at any stage proportional to the loads, and in which the law of superposition does not apply at any stage except, possibly, to stresses at special points or to special deformations. This action differs from pure buckling. The load is a mixed load, and, therefore, the action may be called, properly, mixed buckling. An example is the column loaded endwise and sidewise at the same time. Evidently, each case of mixed buckling is closely related to a corresponding case of pure buckling.

As no general nomenclature has been developed in technical literature for the actions described, it seems desirable to introduce one. The terms, orthostatic, astatic, and heterostatic are proposed for discussions of these actions, and they will be used in this paper. The first term denotes the action in which the law of superposition applies. As this action may be said to represent the regular case, it will be called the orthostatic action.

Fig. 1.

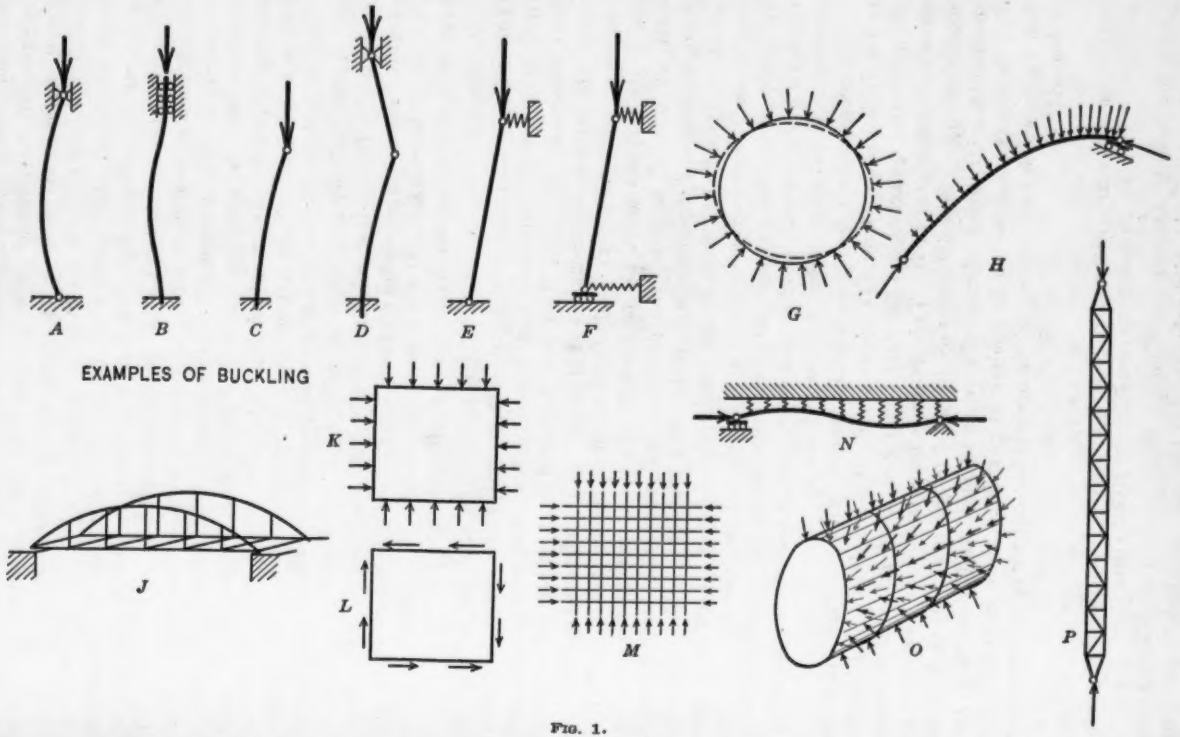

FIG. 1.

The second term will denote the action in which an increase of all loads in the same proportion to critical values produces pure buckling, characterized by a neutral elastic equilibrium. Such action will be called astatic action. This term is explained by the common usage of the word, "astatic", as indicating certain conditions under which a neutral equilibrium is created. The neutral equilibrium is sometimes called an astatic equilibrium, a usage which will be followed by the writer. With the terms introduced, it may be said, for example, that a "neutral or astatic equilibrium characterizes a pure buckling and occurs at certain stages of an astatic action." The third term denotes what has been described as mixed buckling. Such action will be called heterostatic action. Loads producing orthostatic, astatic, and heterostatic actions, respectively, will be referred to as orthostatic, astatic, and heterostatic loads. A heterostatic load, therefore, can be resolved into two components: One an orthostatic load, the other an astatic load. From what has been stated previously, it follows that this investigation will deal mainly with general aspects of astatic action, and with heterostatic action. It will be shown that the cases of heterostatic action can be solved, by certain general formulas, in terms of corresponding cases of astatic and orthostatic actions.

2.—Remarks Concerning the Bibliography.—The classified Bibliography (Part VII) is not intended to include, in general, references dealing exclusively with straight columns which have constant cross-sections and which carry axial end loads only. This case is treated more or less extensively in almost any textbook on Mechanics of Materials. It is sufficient for the present purpose to point to Euler's analysis of columns, which dates back to 1757, and to the progress which has been marked by the introduction of such formulas as that of Rankine, the parabolic, and the straight-line formulas. A large amount of experimental work has been completed in this field. The deviations from Euler's formula are usually explained by the inevitable presence of small initial eccentricities. In fact, some of the textbooks* interpret the formulas mentioned as approximate representations of the secant formula, which applies to eccentric loading and which may be used when some definite "equivalent initial eccentricity" has been introduced.

The comparatively recent work by Kármán on straight columns is quoted in the Bibliography (Part VII, Section *B*). His experiments and analyses are noteworthy on account of the light they throw on the influence of stresses above the proportional limit. This matter is important in the analysis of the shorter columns. Especial attention is called to the treatment of S. Timoshenko of a great variety of cases of pure elastic buckling (Bibliography, Part VII, Section *A*), and also to the analysis of cylindrical shells by Goupil (Section *G*), in which a special case of the general formula for heterostatic action is derived.

II.—Formulas Applying to Columns Which Are Loaded by Axial and by Transverse Forces at the Same Time.

3.—Examples of Applications, Notation, and Current Approximate Formulas.—Straight columns loaded axially and at the same time bent by transverse

* See, for instance, J. E. Boyd, "Strength of Materials," 1917 Edition.

forces are found in many structures. Examples of such columns are as follows: Vertical columns which are loaded sidewise by wind pressure, the latter being transferred to the column either as concentrated forces or as a distributed load; horizontal or inclined compression members which are bent by their own weight; struts in aeroplanes which are bent by wind pressure; and the connecting rod in an engine which is bent by a dynamical action equivalent to a distributed load.

In this Article, and in the subsequent articles, the following notation will be used:

Let l = length of column;

EI = modulus of elasticity times moment of inertia of cross-section;

P = actual axial load;

Q = lowest critical axial load at which buckling would occur. When EI is constant throughout the length, Euler's formula gives: For columns with hinged ends, $Q = \pi^2 \frac{EI}{l^2}$; and for columns with fixed ends, $Q = 4\pi^2 \frac{EI}{l^2}$;

M' = resultant bending moment due to combined pure buckling action and bending, that is, to the combined axial and transverse loads. (M' is the moment in the "mixed" or "heterostatic" action);

M = bending moment when the transverse load acts alone (the moment in the case of orthostatic action).

Indices c and e are used to designate the moments at the center and at the ends, respectively. For instance, M_c = the moment at the center due to the transverse load alone. α, β, and μ are constants entering into the current approximate formulas. Further notation will be introduced in Article 7 (page 589).

Two current approximate formulas will be mentioned. In the first the ratio $\frac{\beta}{\alpha}$ enters. This ratio depends on the distribution of the load and on the end conditions. For example, columns with hinged ends and with a uniform transverse load have $\frac{\beta}{\alpha} = 9.6$; columns with hinged ends and with a concentrated load at the center have $\frac{\beta}{\alpha} = 12$; usually, $\frac{\beta}{\alpha}$ is not very far from 10. With the notation previously given, the formula may be written:*

$$M' = \frac{M}{1 - \frac{\alpha}{\beta}\frac{P\,l^2}{EI}} \qquad (1)$$

In the other approximate formula, the constant, μ, occurs, which is stated as being not very far from unity. Sometimes, $\mu = 1$. The formula† is

$$M' = M\frac{\mu Q}{\mu Q - P} \qquad (2a)$$

* M. Merriman, "Mechanics of Materials," 11th Edition (1915), p. 256.

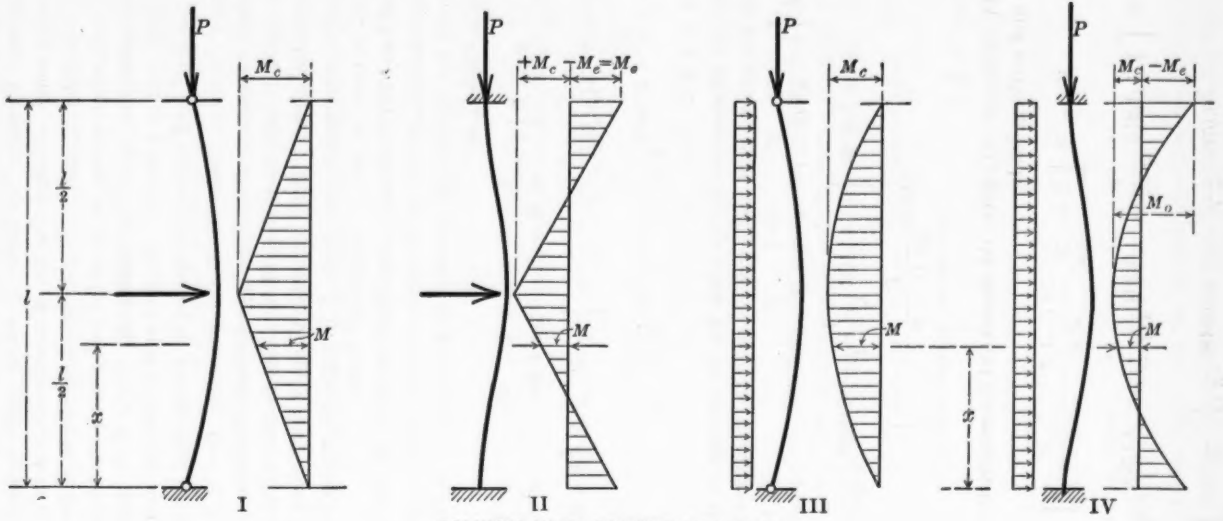
† A. Ostenfeld, "Teknisk Elasticitetslære", 3d Edition (1916), p. 456.

or, when $\mu = 1$,

$$M' = M \frac{Q}{Q - P} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2b)$$

When $\frac{\beta}{\alpha} = \mu \pi^2$, and when $Q = \frac{\pi^2 E I}{l^2}$, Formulas (1) and (2$a$) give identical results. These formulas furnish good approximations in many, but not all, cases.

4.—Proposed Design Formulas for Straight Columns with Uniform Cross-Section.—The theory leading to the formulas proposed here will be discussed later. The exact results are obtained as infinite series, which, however, converge so rapidly that for almost all practical purposes it is sufficient to include only the first two terms of each series. In formulas for design purposes, it is also permissible to simplify the constants entering into them by omitting the less significant decimals.



Four cases which have a particular interest, are shown in Fig. 2. The corresponding proposed design Formulas (3), (3a), (4), (4a), (5), and (6), are given in Table 1.

TABLE 1.—Proposed Design Formulas for Straight Columns.

EI is Assumed to be Constant Throughout the Length. The Limiting Errors Are for Positive *P* (Compression). Cases I, II, III, and IV Are Illustrated in Fig. 2.

		Concentrated load at center.	Uniformly distributed load.
Hinged-end columns: Moments at center, $Q = \frac{\pi^2 E I}{l^2}$.		Case I: $M_c' = M_c \left(1 + 0.8 \frac{P}{Q - P}\right)$ ..(3) (error less than 1.4%).	Case III: $M_c' = M_c \left(1 + 1.03 \frac{P}{Q - P}\right)$ ...(4) (error less than 0.2%) or, approximately, $M_c' = M_c \frac{Q}{Q - P}$ .....(4a) (error less than 3.2%).
Fixed-end columns; $Q = \frac{4\pi^2 E I}{l^2}$.	Moments at center.	Case II: $M_c' = M_c \left(1 + 0.8 \frac{P}{Q - P}\right)$ ..(3) (error less than 1.4%).	Case IV: $M_c' = M_c \left(1 + 1.2 \frac{P}{Q - P}\right)$ ....(5) (error less than 1.3%, and on the safe side; when $\frac{P}{Q} \leq 0.9$, the error does not exceed 1%).
	Moments at ends.	Case II: $M_e' = M_e \left(1 + 0.8 \frac{P}{Q - P}\right)$.(3a) (error less than 1.4%).	Case IV: $M'e = M_e \left(1 + 0.65 \frac{P}{Q - P}\right)$ ...(6) (error less than 6.5% and on the safe side; for $\frac{P}{Q} \leq 0.5$, the error is less than 1%).

If a concentrated load and a distributed transverse load act at the same time, their combined effect can be computed by adding the values given by

COLUMNS WITH TRANSVERSE LOADS

Fig. 2.

the two separate formulas (in Table 1) which apply to these two separate loads; in other words, although the law of superposition does not apply to the total load, consisting of axial loads plus transverse loads, it does apply to the transverse loads alone as long as the axial load retains one constant value.

The formulas also apply, approximately, when P is negative, that is, when the axial load is a tension. In that case a catenary action takes place in which the axial load causes a reduction of the bending moments.

5.—Exact Formulas from Which the Preceding Design Formulas Have Been Derived.—Comparison with the Approximate Formulas.—Formulas (3) to (6), in Table 1, have been derived by simplification of exact expressions given as infinite series. These expressions apply both when P is positive, representing a compression, and when P is negative, representing a tension. P must not be equal to any of the critical loads.

In Cases I and II (Formulas (3) and (3*a*), for M'_c or M'_e and M_c or M_e), the column is loaded transversely at the center, and has fixed or hinged ends. The exact formula for the bending moments at the center in Cases I and II, and at the ends in Case II, is:

$$M'_c \text{ or } M'_e = M_c \text{ or } M_e\left[1 + \frac{8}{\pi^2}\frac{P}{Q-P} + \frac{8}{\pi^2}\frac{1}{3^2}\frac{P}{9\,Q-P} + \frac{8}{\pi^2}\frac{1}{5^2}\frac{P}{25\,Q-P} + \cdots\cdots + \frac{8}{\pi^2}\frac{1}{n^2}\frac{P}{n^2\,Q-P} + \cdots\cdots\right] = M_c \text{ or } M_e\left[1 + 0.811\,\frac{P}{Q-P} + 0.0901\,\frac{P}{9\,Q-P} + 0.0324\,\frac{P}{25\,Q-P} + \cdots\cdots\right] \quad (7)$$

in which $n = 1, 3, 5 \ldots\ldots$

In Case III (Formulas (4) and (4*a*), for the moment at the center, M'_c), the column has hinged ends and carries a uniform transverse load:

$$M'_c = M_c\left[1 + \frac{32}{\pi^3}\frac{P}{Q-P} - \frac{32}{\pi^3}\frac{1}{3^3}\frac{P}{9\,Q-P} + \cdots\cdots \pm \frac{32}{\pi^3}\frac{1}{n^3}\frac{P}{n^2\,Q-P} \mp \cdots\cdots\right] = M_c\left[1 + 1.032\,\frac{P}{Q-P} - 0.0382\,\frac{P}{9\,Q-P} + 0.0083\,\frac{P}{25\,Q-P} - \cdots\cdots\right] \quad (8)$$

in which $n = 1, 3, 5 \ldots\ldots$

Case IV (Formula (5)), gives the moment at the center, for a column with fixed end and uniform load:

$$M'_c = M_c\left[1 + \sum_{1,2,3\ldots}^{n} \frac{12\,(-1)^{n-1}}{\pi^2 n^2}\frac{P}{n^2\,Q-P}\right] = M_c\left[1 + 1.216\,\frac{P}{Q-P} - 0.304\,\frac{P}{4\,Q-P} + 0.1352\,\frac{P}{9\,Q-P} - 0.0760\,\frac{P}{16\,Q-P} + 0.0486\,\frac{P}{25\,Q-P} \cdots\cdots\right] \quad (9)$$

Case IV (Formula (6)), gives the moments at the ends for a fixed-end column, with uniform load:

$$M'_e = M_e \left[1 + \sum_{1,2,3\ldots}^{n} \sum_{1,2,3\ldots}^{m} \frac{6}{\pi^2 n^2} \frac{P}{n^2 Q - P} \right]$$

$$= M_e \left[1 + 0{,}608 \frac{P}{Q - P} + 0.1520 \frac{P}{4 Q - P} + 0.0676 \frac{P}{9 Q - P} \right.$$

$$\left. + 0.0380 \frac{P}{16 Q - P} + 0.0243 \frac{P}{25 Q - P} \cdots \right] \ldots\ldots\ldots (10)$$

The limiting errors indicated in Table 1 are found by comparison with the exact Formulas (7) to (10). Formula (6), derived from Formula (10), gives the greatest deviation. However, the error remains less than 1% when $\frac{P}{Q} \leq 0.5$. A quite satisfactory approximation is obtained by using the first three terms in Formula (10), which may then be written in the simplified form:

$$M'_e = M_e \left[1 + 0.6 \frac{P}{Q - P} + 0.2 \frac{P}{4 Q - P} \cdots \right] \ldots\ldots\ldots (10a)$$

Formulas (7) to (10) are rapidly converging series. For instance, $P = 0.5Q$, that is, the actual axial load equal to one-half of the critical axial load, gives the following values of $\frac{M'}{M}$, when two, three, or four, etc., terms of each series are included:

From Formula (7): 1.811, 1.816, 1.817, 1.817, ...
From Formula (8): 2.032, 2.030, 2.030, ...
From Formula (9): 2.216, 2.173, 2.181, 2,179, 2.180, ...
From Formula (10): 1.608, 1.630, 1.634, 1.635, 1.635, ...

The approximation obtained with the current approximate Formulas (1), (2*a*), and (2*b*), will now be examined in a typical case. Consider a hinged-end column loaded by a concentrated transverse force at the center. In that case, $\frac{\beta}{\alpha} = 12$. This value corresponds to $\mu = \frac{12}{\pi^2}$ in Formula (2*a*). The deviations from the exact values are then in percentage:

For $\frac{P}{Q}$ ..... =	0.2	0.5	0.9	1.0 (limiting case):
Deviations by using Formulas (1) and (2*a*) ..... =	— 1%	— 7%	— 54%	— 100%
Deviations by using Formula (2*b*) ... =	+ 4%	+ 10%	+ 20%	+ 23%

This comparison bears out the desirability of a revision of the current formulas. It must be stated, though, that, on account of the rapid variations

of M' when $\frac{P}{Q}$ approaches unity, the great deviations when $\frac{P}{Q} = 0.9$ or 1.0 are of comparatively less significance than the errors at smaller values of $\frac{P}{Q}$.

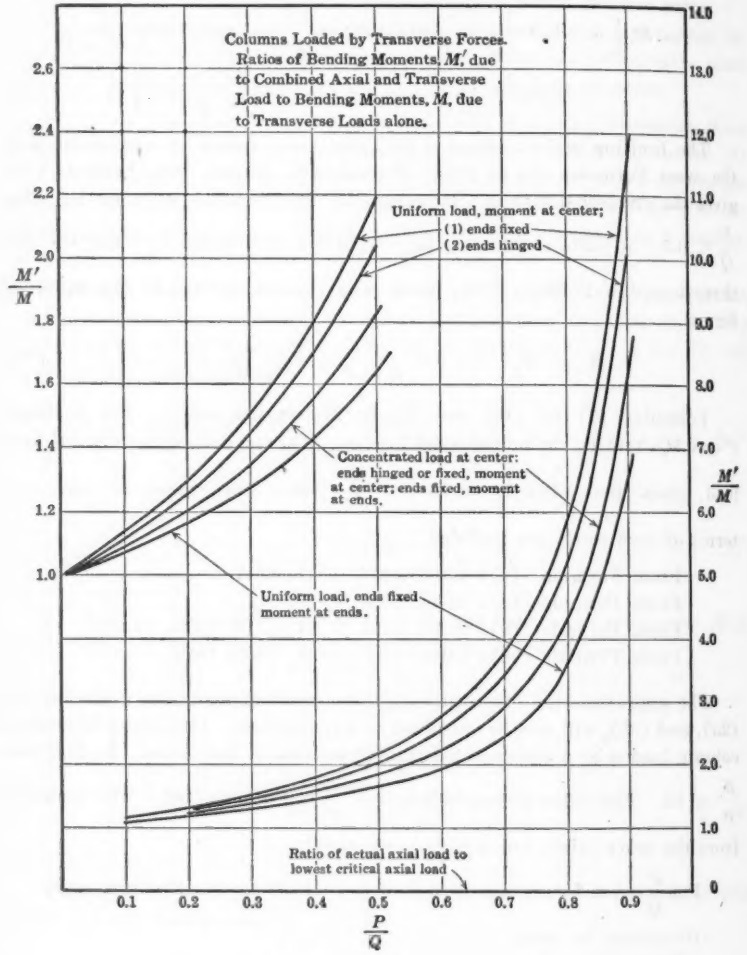


FIG. 3.

6.—Tabulated Numerical Results.—Graphs.—Table 2 is computed by Formulas (7) to (10). Fig. 3 represents the same data graphically.

7.—A More General Formula from Which the Preceding Formulas Have Been Derived.—The notation given in Article 3 is here supplemented, as follows:

Q_1, Q_2, $Q_3 \ldots Q_n \ldots$ = series of critical axial loads at which buckling (astatic elastic equilibrium) can take place. Q_1 is equal to Q in the preceding formulas. When both ends are fixed or both ends hinged, and when the cross-section is constant, then $Q_n = n^2 Q$. As mentioned in the Introduction, the neutral or astatic equilibria corresponding to the higher critical loads are unstable equilibria.

TABLE 2.—RATIOS, $\frac{M'}{M}$, OF TOTAL MOMENTS TO MOMENTS DUE TO TRANSVERSE LOADS ALONE FOR VARIOUS VALUES OF $\frac{P}{Q}$.

P = Axial Load; for Hinged Ends, $Q = \frac{\pi^2 E I}{l^2}$; for Fixed Ends, $Q = \frac{4 \pi^2 E I}{l^2}$.

Load:	Concentrated at Center.		Distributed.		
Ends:	Hinged.	Fixed.	Hinged.	Fixed.	
Moment at:	Center.	Ends or center.	Center.	Center.	Ends.
$\frac{P}{Q} = 0$	1.000		1.000	1.000	1.000
0.1	1.091		1.114	1.129	1.073
0.2	1.205		1.257	1.290	1.163
0.3	1.351		1.442	1.502	1.277
0.4	1.546		1.686	1.782	1.428
0.5	1.817		2.030	2.18	1.636
0.6	2.223		2.545	2.78	1.95
0.7	2.901		3.405	3.78	2.46
0.8	4.25		5.18	5.79	3.48
0.9	8.31		10.29	11.87	6.52
1.0	∞		∞	∞	∞

M_1, M_2, $M_3 \ldots M_n \ldots$ = bending moments in the column which have the following properties: First, each of the moments, $M_1 \ldots\ldots M_n \ldots\ldots$, is a function of the distance measured along the column, and may be represented by a diagram having the length of the column as a base; second, the diagram, M_n, is the moment diagram at a certain stage of the buckling or astatic action in which Q_n is the critical load; it is easily verified that if M_n is such a moment diagram, belonging to the buckling action the critical load of which is Q_n, then M_n multiplied by any constant factor will be another moment diagram belonging to the same buckling action, with the critical load Q_n; the greater this factor, the further progressed is the stage of this buckling; and, third, the moments, $M_1 \ldots M_n \ldots$, are so chosen by properly choosing the stages of buckling under each of the loads, $Q_1 \ldots Q_n \ldots$, respectively, that the total moment due to the transverse loads may be expressed by the following relation, which is to apply at all points of the column:

$$M = M_1 + M_2 + \ldots\ldots + M_n + \ldots\ldots\ldots\ldots\ldots (11)$$

It will be shown later that it is possible, in general, to do this. When it is possible to establish the relation, Formula (11), it may be done by mutiplying any set of moment diagrams which are proportional to M_1, M_2, $\ldots M_n \ldots$ and which are produced in astatic actions, by a proper set of factors.

The more general formula from which Formulas (7) to (10) have been derived, will now be indicated. The derivation of the formula will follow later (Part IV). The formula has a wide field of application, but will appear in Part IV as a special case of a still more general formula which applies to any heterostatic action. The formula applies primarily to those cases of axially and transversally loaded straight columns in which the supports do not absorb any elastic energy, that is, it applies, for example, when the ends are fixed or simply supported (hinged), or when one end is free and the other end fixed, and also when there are inelastic supports at intermediate points. The formula also applies, in general, even when the supports are elastic, but in that case some qualifications must be introduced as to the make-up of the functions, $M_1 \ldots\ldots M_n \ldots\ldots$ This result will follow from the general theory in Part IV. The formula applies whether the cross-section is constant or varies, or whether the axial load is applied at the ends or at other points. The formula is:

$$M' = M + M_1 \frac{P}{Q_1 - P} + M_2 \frac{P}{Q_2 - P} + \ldots\ldots + M_n \frac{P}{Q_n - P} + \ldots\ldots (12)$$

The essential difficulty in the use of Formula (12) lies in the determination of the functions, $M_1 \ldots\ldots M_n \ldots\ldots$ The writer will now show how these difficulties are overcome in various specific cases.

8.—Deriving the Specific Formulas from the General Formula.—The formulas applying to the four cases in Fig. 2 will now be derived from the general Formula (12). The cross-section is again assumed to be constant, and the same typical method will be seen to apply in all four cases.

Case I.—Hinged-end column, carrying a concentrated transverse load at the center (Fig. 2 (I)): The formula which is to be derived is Formula (7). The derivation of the approximate Formula (3) from Formula (7) was indicated in Article 5.

The first step is to find the deflections and the bending moments in the buckling actions in which $Q_1, Q_2 \ldots\ldots Q_n \ldots\ldots$ are the critical loads. To the critical load, Q_n, corresponds a buckling curve or curve of deflections consisting of n half waves. From the theory of columns, as given in texts on Mechanics of Materials, this curve is known to be a sine wave. The bending moments are found as the second derivatives of the deflections multiplied by the constant factor, $\pm EI$. It follows also that the moment diagram, M_n, will be shaped as a sine curve with n half waves. Let x be the distance measured along the column from the lower end; then the equation for M_n may be written:

$$M_n = C_n \sin \left(\frac{n \pi x}{l}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

where C_n is a constant. The bending moment, M, due to the transverse load alone, should now be expressed in the form of the series, $M = \Sigma M_n$ (Formula (11)). M is given by the triangular moment diagram in Fig. 2 (I). The series, ΣM_n, is a trigonometric series. From the theory of Fourier series* it is known that any diagram can be represented by an infinite trigonometric series (Fourier series). It is possible, therefore, to find a set of constants, C_n,

* For instance, Byerly, "Harmonic Functions", 4th ed. (1906).

which, introduced into Formula (13), make $M = \Sigma M_n$. From the theory of Fourier series, we have:

$$C_n = \frac{2}{l} \int_0^l M \sin \left(\frac{n \pi x}{l} \right) d x \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

Substituting the values for M given in Fig. 2 (I), integrating, and forming the expressions for M_n, we find:

$$\text{for } n \text{ even}, \quad M_n = 0$$

$$\text{for } n \text{ uneven}, \quad M_n = (-1)^{\frac{n-1}{2}} \frac{8}{\pi^2} \frac{M_c}{n^2} \sin \frac{n \pi x}{l}.$$

Hence, the series for M may be written:

$$M = \Sigma M_n = M_c \left[\frac{8}{\pi^2} \sin \frac{\pi x}{l} - \frac{8}{\pi^2} \frac{1}{3^2} \sin \frac{3 \pi x}{l} + \frac{8}{\pi^2} \frac{1}{5^2} \sin \frac{5 \pi x}{l} - \ldots\ldots\ldots \right]$$

The expressions for M_n appear in this series with the constant factor, M_c. By substituting these expressions for M_n in Formula (12) and by putting $Q_n = n^2 Q$, the following formula is found for the moment, M', produced at any point, under the combined influence of the transverse and the axial load:

$$M' = M + M_c \left[\frac{8}{\pi^2} \frac{P}{Q - P} \sin \frac{\pi x}{l} - \frac{8}{\pi^2} \frac{1}{3^2} \frac{P}{9\,Q - P} \sin \frac{3 \pi x}{l} \right.$$

$$\left. + \frac{8}{\pi^2} \frac{1}{5^2} \frac{P}{25\,Q - P} \sin \frac{5 \pi x}{l} - \ldots\ldots\ldots\ldots \right]$$

We are particularly interested in the maximum moment, which occurs at the center. At that point, n uneven gives $\sin \frac{n \pi x}{l} = \pm 1$. The substitution of these values, ± 1, in the foregoing equation for M' leads directly to Formula (7) which was to be derived.

The other cases, II, III, and IV, in Fig. 2, for which special formulas have been given, can be treated in a similar manner. In all cases, the moment diagrams, M_n, in pure buckling action (astatic action) are trigonometric diagrams, and the series, ΣM_n, are Fourier series which represent the triangular and parabolic moment diagrams given in Fig. 2. Each of these cases will now be discussed.

Case II.—Column with fixed ends, and with a transverse load at the center: In the deflected curve, the quarter-points will be points of inflection. The column will be in equilibrium when the middle half is bent according to the laws applying to the whole length in Case I, and the outer quarters of the length will be bent into the same shape as the middle quarters. It follows that Formula (7) applies also to this case and expresses both the moments at the ends and at the center.

Case III.—Hinged ends, uniform transverse load: Formulas (13) and (14) apply also to this case, only, the values of M are to be taken from the parabolic moment diagram. M_n is found to be:

$$\text{for } n \text{ even}, \quad M_n = 0$$

$$\text{for } n \text{ uneven}, \quad M_n = \frac{32}{\pi^3} \frac{M_c}{n^3} \sin \frac{n \pi x}{l}$$

The substitution of these values, with $x = \frac{l}{2}$, in the general Formula (12), leads to Formula (8).

Case IV.—Fixed ends, uniform transverse load: When the distance, x, is measured from the center, we find:

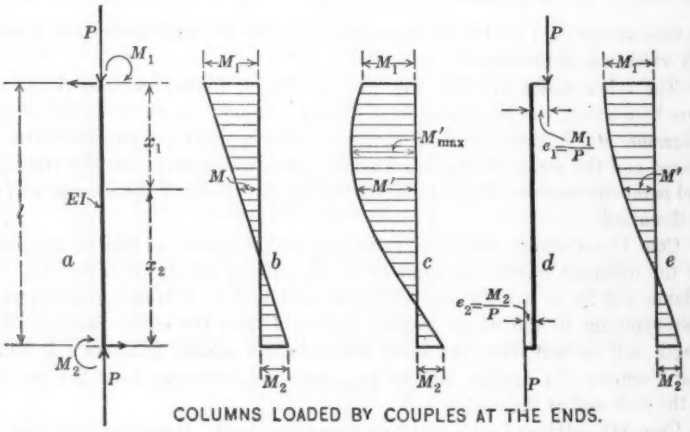
$$M = M_0 \left(\frac{1}{3} - \frac{4\,x^2}{l^2}\right)$$

where,

$$M_0 = 3\,M_c = -1.5\,M_e$$

M_n takes the form:

$$M_n = C_n \cos n \left(\frac{2\,\pi\,x}{l}\right)$$



where, by the theory of Fourier series:

$$C_n = \frac{2}{l} \int_{-\frac{l}{2}}^{+\frac{l}{2}} M \cos n \left(\frac{2\,\pi\,x}{l}\right) d\,x$$

After integration, we find in this manner:

$$M_n = (-1)^{n-1} \frac{4\,M_0}{\pi^2\,n^2} \cos \frac{n\,2\,\pi\,x}{l}$$

Substitution of these values in the general Formula (12), with $x = 0$ and $x = \frac{l}{2}$, leads to Formulas (9) and (10).

COLUMNS LOADED BY COUPLES AT THE ENDS.

FIG. 4.

9.—Columns Loaded by Couples at the Ends.—The column in Fig. 4 (*a*) carries a central axial load, P, and at the same time is loaded by the couples, M_1 and M_2, which act at the ends, and are considered as positive in clockwise direction. The cross-section is assumed to be constant. This problem may be

treated by means of the general Formula (12) in the same manner as the preceding cases, but the particular conditions of the present problem allow a rather simple direct solution, which will now be indicated.* Let the notation for distances be as shown in Fig. 4 (*a*). The moment diagram produced by the couples alone is shown in Fig. 4 (*b*). In the combined bending and buckling action the resultant moment diagram may shape itself as shown in Fig. 4 (*c*). Evidently, the same action might be produced by the forces, P, alone, namely, when they are applied with the eccentricities indicated in Fig. 4 (*d*).

The particular object is to find the maximum values of the moments, M'. This may be done as follows: M' is expressed in terms of M_1, M_2, x_1, and P, and the deflections, y. The expression formed in this manner is substituted in the flexure equation, $E\,I\,\frac{d^2y}{d\,x_1^2} = -\,M'$, which is then integrated, whereupon M' is found by a double differentiation. The quantities are introduced:

$$Q = \frac{\pi^2\,EI}{l^2} = \text{lowest critical axial load when ends are hinged;}$$

and,

$$k = \frac{P}{Q}$$

The formula found for M' at any point is then:

$$M' = \frac{M_1 \sin \pi \left(\frac{x_2}{l}\right) \sqrt{k} - M_2 \sin \pi \left(\frac{x_1}{l}\right) \sqrt{k}}{\sin \pi \sqrt{k}} \quad \ldots\ldots\ldots (15)$$

M' becomes maximum or minimum when $\frac{d\,M'}{d\,x_1} = 0$. Since, $dx_1 = -\,dx_2$, the derivative becomes zero when,

$$\cos \pi \left(\frac{x_2}{l}\right) \sqrt{k} + \left(\frac{M_2}{M_1}\right) \cos \pi \left(\frac{x_1}{l}\right) \sqrt{k} = 0 \quad \ldots\ldots\ldots (16)$$

Formula (16) is adaptable to graphical solution.

It may happen that no solution of Formula (16) occurs within the length of the column. In that case, if M_2 is numerically smaller than M_1, the moment, M', will decrease on the whole length of the column from the top to the bottom. The case is represented in Fig. 4 (*e*), where the value, M_1, of the end moment is the greatest value of M'. The case occurs when the axial load, P, is comparatively small, that is, when k is comparatively small. The limiting case is found by inserting $x_1 = 0$, $x_2 = l$ in Formula (16), whereby we find,

$$\cos \pi \sqrt{k} + \frac{M_2}{M_1} = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

For each value of $\frac{M_2}{M_1}$ between $+1$ and -1, a corresponding limiting value of $k = \frac{P}{Q}$ may be found from Formula (17). At and below this limiting

* For the derivation of the deflected curve see A. Ostenfeld, "Teknisk Elasticitetslære", 3d ed. (1916), p. 452. The case is important with regard to the question of shearing stresses in columns (*ibid*, p. 453).

value, we have max. $M' = M_1$. Above the limiting value of k, the values of x_1 and x_2 found from Formula (16), are to be substituted in Formula (15), thereby giving a value of max. M'.

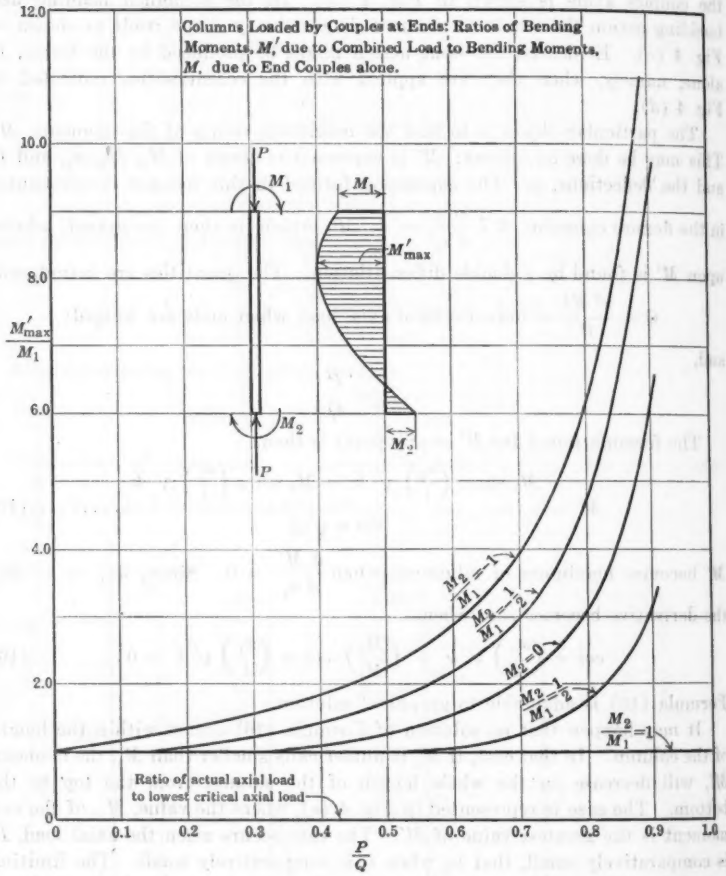


FIG. 5.

Three special cases will be examined, namely, $M_2 = -M_1$, $M_2 = 0$, and $M_2 = M_1$, respectively. First, assume $M_2 = -M_1$: In this case the moment due to the end couples alone is constant throughout the length. The case may be produced by eccentric loading with the same eccentricity, to the same side, at the top, and at the bottom. Formula (16) gives, in this case, $x_1 = x_2 = \frac{l}{2}$,

that is, as would be expected, the greatest moment occurs at the center. Formula (15) gives then:

$$\text{max. } M'_{M_2=-M_1} = \frac{2\,M_1 \sin \frac{\pi}{2}\sqrt{k}}{\sin \pi \sqrt{k}} = M_1 \sec \frac{\pi}{2}\sqrt{k} \quad \ldots\ldots(18)$$

This equation is a form of the secant formula which applies to eccentric loading. The second special case, $M_2 = 0$, occurs when the column is hinged at the lower end. Formulas (15) and (16) give:

$$\text{max. } M'_{M_2=0} = \frac{M_1}{\sin \pi \sqrt{k}} \text{ at point } x_2 = \frac{l}{2\sqrt{k}} \quad \ldots\ldots(19)$$

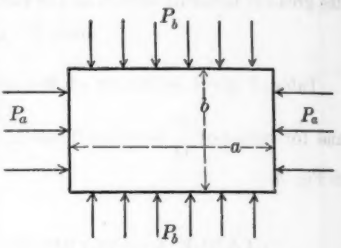
In the third special case, $M_1 = M_2$, Formula (17) gives $k = 1$ as the limiting value. It follows that for all values of P less than the critical load, Q, the greatest moment occurs at the ends, that is,

$$\text{max. } M'_{M_2=M_1} = M_1 \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (20)$$

Table 3 gives solutions of the preceding formulas for various values of $\frac{M_2}{M_1}$ and for values of $\frac{P}{Q}$ between 0 and 1. The same data are presented graphically in Fig. 5.

TABLE 3.—Columns Bent by Couples at the Ends.

$\frac{x_1}{l}$ = Ratio of Distance from Upper End to Point of Maximum Moment;



$\frac{M'}{M_1}$ = Ratio of Maximum Moment to Moment at Top;

$Q = \frac{\pi^2 EI}{l^2}$; otherwise, the notation is as given in Fig. 5.

$\frac{P}{Q}$	$M_2 = -M_1$		$M_2 = -\frac{1}{2}M_1$		$M_2 = 0$		$M_2 = \frac{1}{2}M_1$		$M_2 = M_1$

III.—Slabs and Similar Structures.

10.—Formulas Applying to Rectangular Homogeneous Slabs.—A rectangular slab may buckle under the influence of loads at the edges acting in the original plane of the slab. Two examples of this kind were mentioned in the Introduction (Fig. 1 (*K*) and Fig. 1 (*L*)). In the one case, the load was perpendicular to the edge; in the other, it was parallel to the edge. Until the deflections have become quite large, the action is a typical astatic elastic action (pure buckling). Loads from the side, perpendicular to the slab, acting alone, produce orthostatic action, that is, ordinary flexure with the deformations proportional to the loads. A combination of the end loads in the plane of the slab and the side loads produces mixed or heterostatic action. When the frames of a ship are rather widely spaced, such actions may become important in the shell (deck, sides, and bottom). Cases of buckling of rectangular slabs have been analyzed by Messrs. G. H. Bryan, S. Timoshenko, and others, and reference is made to the treatments by these authors (Bibliography, Part VII, Sections *A* and *J*). The material presented by the writer will include some cases of buckling or astatic action as well as some cases of mixed or heterostatic action.

SLAB WITH BUCKLING LOADS.
FIG. 6.

Let (Fig. 6), a = longer span;
b = shorter span;
$\alpha = \frac{b}{a}$

EI = modulus of elasticity times moment of inertia of cross-section per unit width;

K = Poisson's ratio of lateral contraction to longitudinal elongation when a longitudinal load acts alone;

w = uniformly distributed load per unit area, perpendicular to the surface of the slab;

P_a = uniformly distributed compressive end load per unit width, acting at the short edges in the direction of the long span. A negative P_a represents tension;

P_b = uniformly distributed compressive end load per unit width, acting at the long edges in direction of the short span;

Q_a and Q_b = critical values of the end loads found by increasing the original values of P_a and P_b by the same ratio until buckling can take place without the aid of the surface load, w;

M = moment in slab per unit width in the orthostatic action, in which the surface load, w, is the only external load;

M' = moment in the mixed or heterostatic action in which end loads, such as P_a and P_b, act at the same time as the surface load, w;

$M'' = M' - M$ = increase of moment produced by application of the end load when the surface load is already acting;

M_b, M'_b, M''_b = values of M, M', and M'' at the center of the slab, for bending in the short span, b (that is, in an element of section perpendicular to the short span, b);

m, n = positive integers.

The writer will confine himself to cases in which the only end loads in the plane of the slab are those perpendicular to the edges, such as, P_a and P_b in Fig. 6. It is assumed that each rectangular panel can be treated separately, and, accordingly, only one single independent panel will be considered. The slab is assumed to be homogeneous, isotropic, and sufficiently thin so that it may begin to buckle without exceeding the elastic limit. It is also assumed that the deflections have not progressed so far as to affect the uniformity of the distribution of the pressures in the plane of the slab. The slab under consideration has simple supports along the four edges, and these supports hold the edges in the original plane of the slab.

The writer will again follow the plan of presenting results first. The derivations follow later, in Parts IV and V.

A.—Astatic Action, Buckling Due to End Loads Alone, When the Slab is Simply Supported.

An astatic (neutral) equilibrium may occur when the end loads, Q_a and Q_b, satisfy the condition:

$$\frac{m^2 Q_a}{a^2} + \frac{n^2 Q_b}{b^2} = \frac{\pi^2 E I}{1 - K^2}\left[\frac{m^2}{a^2} + \frac{n^2}{b^2}\right]^2 \quad \ldots\ldots\ldots\ldots (21)$$

where $m, n = 1, 2, 3 \ldots\ldots$*. The lowest critical values of Q_a and Q_b have the greatest interest, as they are the values at which the actual buckling would take place if the load was increased gradually from zero. In buckling caused by the lowest critical loads, one of the integers, m and n, is always equal to 1. The values of m and n, and the corresponding solutions of Formula (21), will now be indicated in some definite cases.

Case 1.—Square slab, $a = b$:

a.—Q_b positive, $Q_a = 0$ (compression in direction of one span only):

$$m = n = 1$$

Formula (21) gives,

$$Q_b = \frac{4 \pi^2 E I}{(1 - K^2) b^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (22)$$

b.—Q_a and Q_b both positive (both compressive loads):

$$m = n = 1$$

In this case, Formula (21) becomes,

$$Q_a + Q_b = \frac{4 \pi^2 E I}{(1 - K^2) b^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

* Formula (21) was given by G. H. Bryan, *Proceedings*, London Math. Soc., v. 22 (1890), p. 57; see, also, A. E. H. Love, "Mathematical Theory of Elasticity" (1906), p. 529.

c.—Q_b positive, $Q_a = -Q_b$ (that is, Q_a is a tension equal in magnitude to the compression, Q_b). This case is of some importance because it represents the condition of pure shear in the directions of the diagonals:

$$m = 1, n = 2$$

Substitution of these values in Formula (21) gives:

$$Q_b = \frac{25\,\pi^2\,E\,I}{3\,(1 - K^2)\,b^2} \qquad (24)$$

d.—Q_b positive, $Q_a = -2Q_a$:

$$m = 1, n = 2;\ Q_b = \frac{25\,\pi^2\,E\,I}{2\,(1 - K^2)\,b^2}$$

e.—General case, Q_b positive, ratio $\frac{Q_a}{Q_b}$ any value:

$$m = 1;\ Q_b = \frac{\pi^2\,E\,I}{(1 - K^2)\,b^2}\,\frac{(n^2 + 1)^2}{n^2 - \left(-\frac{Q_a}{Q_b}\right)} \qquad (25)$$

$$n = 1 \text{ when } -\frac{Q_a}{Q_b} < 0.43$$

$$n = 2 \text{ when } 0.43 < -\frac{Q_a}{Q_b} < 2.33$$

$$n = 3 \text{ when } 2.33 < -\frac{Q_a}{Q_b} < 5.30$$

Case 2.—Rectangular slab, $a > b$. $Q_a = 0$, that is, the load is in the direction of the short span only:

$$m = n = 1;\ Q_b = \frac{\pi^2\,E\,I\,(1 + \alpha^2)^2}{(1 - K^2)\,b^2} \qquad (26)$$

It is noted that the limiting case, $\alpha = 1$, leads to Formula (22). $\alpha = 0$, that is, $a = \infty$, and Poisson's ratio, $K = 0$, gives the usual Euler formula for columns, $Q = \frac{\pi^2\,E\,I}{b^2}$.

Case 3.—Rectangular slab, $a > b$. $Q_b = 0$, that is, the load is in the direction of the long span only:

$$n = 1;\ Q_a = \frac{\pi^2\,E\,I}{(1 - K^2)\,b^2}\,\frac{(m^2\,\alpha^2 + 1)^2}{m^2\,\alpha^2} \qquad (27)$$

When $\frac{1}{\alpha}$ is an integer, then $m = \frac{1}{\alpha}$. Otherwise, m = either the nearest integer above, or the nearest integer below, $\frac{1}{\alpha}$. This result may be proved by considering m as varying continuously; then Q_a in Formula (27) is found to have a minimum when $m = \frac{1}{\alpha}$. This result means physically that in the buckling of the center line of the long span, the half-wave length (distance between points of inflection) has a tendency to become equal to the shorter

span of the slab. Under any circumstance, $m\ \alpha = 1$ substituted in Formula (27) defines a lower limit of the critical load, namely,

$$Q_a = \frac{4\ \pi^2\ E\ I}{(1 - K^2)\ b^2} \qquad (27a)$$

In most cases Formula (27*a*) would replace Formula (27) with good approximation.

Case 4.—General case: Rectangular slab, $b < a$, $\frac{Q_a}{Q_b}$ = any value. The general Formula (21) is to be used. It was stated that in order to obtain the lowest critical loads one of the integers, m and n, must always be equal to 1. The following rule applies:

$$m = 1 \text{ when } \frac{Q_a}{Q_b} < 0.5,\ Q_b > 0;$$
$$n = 1 \text{ when } Q_a \geqq 0.$$

The general Formula (21) is the equation of a straight line in the coordinate system, Q_a, Q_b (Fig. 7). By keeping m constant, but varying n, a set of straight lines is obtained all of which are tangents to the same parabola with the axis parallel to the Q_a-axis. In the same way, variation of m while n is kept constant, gives a set of tangents to a parabola with the axis parallel to the Q_b-axis. Two such sets of tangents, one for $m = 1$ and one for $n = 1$, form a polygon which defines the lowest critical values, Q_a and Q_b, for all ratios, $\frac{Q_a}{Q_b}$. The two parabolas pass through the origin with their tangents making angles of 45° with the axes. The parabolas are open backward and downward. Fig. 7 shows the parabolas for the cases of the square slab, $a = b$, and the rectangular slab, $a = 2\ b$. The vertices of the polygons represent conditions under which two different buckling waves may be superimposed, one on the other, so that a double, neutral equilibrium occurs at those particular loads.

B.—Orthostatic Flexure, Bending Without End Loads in the Plane of the Slab, the Slab Being Simply Supported Along the Four Edges.

The surface load, w, is acting, but there are no pressures from the ends. It will be assumed temporarily that Poisson's ratio, K, of lateral contraction to longitudinal stretch is zero. The moment at the center in Span b is then found to be given approximately by the following formula:

$$M_b = \frac{\frac{1}{8}\ w\ b^2}{1 + \alpha^2 + 1.4\ \alpha^4} \qquad (28)$$

In a slab which is square or nearly square greater moments occur along and across the diagonals at the corners than at the center. Formula (29) may be used with advantage in many cases. It gives a reasonable approximation to the maximum moment in the slab. In slabs which are nearly square, it gives somewhat too low stresses, but a slight local yielding at the corners

will re-distribute the stresses until values almost similar to those given by the formula are obtained:*

$$M = \frac{\frac{1}{8} w b^2}{1 + 2\alpha^3} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

It is noted that $\frac{b}{a} = \alpha = 1$ would give $M = \frac{1}{24} w b^2$, which is a value often used for square slabs. When Poisson's ratio, K, is different from zero, Formulas (28) and (29) indicate the product of the curvature (second derivative of the deflections) times the stiffness ratio, $\frac{E I}{(1 - K^2)}$. According to the "strain theory" of rupture—St. Venant's theory—$E I$ times the curvature will be the moment quantity indicating the tendency to rupture. Accordingly, if this theory could be assumed to hold, Formulas (28) and (29) multiplied by $(1 - K^2)$ could be used as "theoretical moments" measuring the nearness of rupture.

C.—Heterostatic (Mixed) Action.

Poisson's ratio, K, is again assumed to be equal to zero. The difference brought about by Poisson's ratio not being zero is of the same nature as that described for the case of orthostatic flexure. An approximate formula will be indicated for the additional bending moment, M''_b, in Span b at the center. The approximation is close only when the combination $m = n = 1$ in Formula (21) leads to the lowest critical end loads, Q_a and Q_b. Formula (30) is similar to the approximate formulas mentioned previously for columns. It is derived from the general theory which follows later (Part IV), with use made of a solution of a differential equation of flexure given in Part V (Formula (150)). The formula is:

$$M''_b = \frac{16}{\pi^4} \frac{w b^2}{(1 + \alpha^2)^2} \frac{P_a}{Q_a - P_a} = \frac{16}{\pi^4} \frac{w b^2}{(1 + \alpha^2)^2} \frac{P_b}{Q_b - P_b} \quad \ldots\ldots (30)$$

This value is to be added to M_b in Formula (28), and gives thereby the combined moment, M'_b. It will be on the safe side to compute a value of the maximum moment, M', at any point by adding M''_b to the maximum orthostatic moment, M. Taking M from Formula (29) and substituting $\frac{16}{\pi^4} = 0.164$, the combined maximum moment, one finds:

$$M'_{\max.} = M + M'' = \frac{\frac{1}{8} w b^2}{1 + 2\alpha^3} + \frac{0.164\, w b^2}{(1 + \alpha^2)^2} \frac{P_a}{Q_a - P_a} \quad \ldots\ldots (31)$$

* Formula (28) follows rather closely values given by A. Nádai, in "Die Formänderungen und Spannungen von rechteckigen elastischen Platten", *Mitteilungen* über Forschungsarbeiten auf dem Gebiete des Ingenieurwesens, Vol. 170–171, table, p. 34, provided correction is made for the effect of Poisson's ratio. A formula similar to Formula (28) is indicated in a note on the design of reinforced concrete, issued by the French Council on Bridges and Roads, entitled, "Calcul des Hourdis en Béton Armé", *Annales des Ponts et Chaussées*, 1912, IV, pp. 469–529 (see in particular, p. 474). Mesnager indicates a formula which is similar to Formula (29), see his memoir, "Moments et Flèches des Plaques Rectangulaires Minces Portant une Charge Uniformément Répartie", *Annales des Ponts et Chaussées*, 1916, III, pp. 313–438 (see in particular p. 436 and Plate VII). The derivation of the differential equation of flexure, on the solutions of which these analyses depend, is indicated in Part V, Article 31, of this investigation.

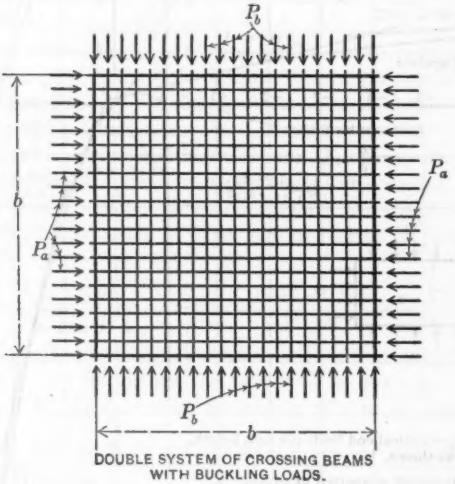
The slab is simply supported at edges.
m = number of half-wave lengths in buckling of Span a.
n = same in Span b.
The straight lines determine the critical loads.

FIG. 7.

Formula (31) applies with the same limitations as Formula (30). In the case of a square slab, we have $\alpha = 1$. In that case, Formula (31) gives:

$$M'_{\max.} = \frac{1}{24}\, w\, b^2 + 0.041\, w\, b^2 \frac{P_a}{Q_a - P_a}$$



that is, with sufficiently close approximation,

$$M'_{\max.} = \frac{w\, b^2}{24} \frac{Q_a}{Q_a - P_a} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (32)$$

When one of the integers m and n is different from 1, Formulas (30), (31), and (32), with Q_a and Q_b taken as the lowest critical loads, will lead to values which are in most cases decidedly higher than the actual values. However, in all such cases, as well as in those in which Formulas (30) to (32) apply, Formula (33) will be on the safe side, or only slightly on the unsafe side:

$$M' = M \frac{Q_a}{Q_a - P_a} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (33)$$

Formula (33) has the same form as the current approximate Formula (2*b*) in Article 3 and Formula (4*a*) in Article 4.

DOUBLE SYSTEM OF CROSSING BEAMS WITH BUCKLING LOADS.

FIG. 8.

11.—Formulas Applying to a Double System of Crossing-Beams Connected at Cross-Points.—Fig. 8 shows two systems of beams crossing one another at right angles and arranged in a square. The beams are simply supported at the edges of the square so that these edges must remain in their original plane. The beams are connected at the cross-points so as to make the deflections of the two beam systems the same without causing any torsional moments in the beams. A great number of beams are assumed, uniformly spaced and with uniform stiffness. The end loads on each beam system are evenly distributed, and are transmitted directly to each beam as axial loads, so as to give a

constant total axial pressure in any section of any beam. The structure resembles a slab, but the difference lies in the lack of torsional resistance in the double-beam system. This quality is demonstrated by the fact that one could lift one of the corners out of the original plane, and thereby produce a double curved surface, without putting stresses in any of the beams. It may be interesting to investigate this case for the purpose of comparison with the homogeneous slab. A square concrete slab with reinforcing bars parallel to the edges has properties intermediate between those of the homogeneous slab and those of the double-beam system, and the resistance of two-way reinforced concrete against buckling might be estimated by comparison with the two extreme cases.

The same notation will be used as in Article 10. The loads, moments, and the stiffness factor, $E\,I$, are indicated per unit width of section. It will be assumed that the spacing of the beams is so close that the area elements of the structure may be considered as continuous.

A.—Astatic Action.

The general formula for buckling, to be compared with Formula (21) in Article 10, is

$$m^2\,Q_a + n^2\,Q_b = \frac{\pi^2\,E\,I\,(m^4 + n^4)}{b^2} \quad \ldots\ldots\ldots\ldots\ldots (34)$$

When both Q_a and Q_b are positive, the buckling at the lowest load is represented by $m = n = 1$. In this case, Formula (34) becomes:

$$Q_a + Q_b = \frac{2\,\pi^2\,E\,I}{b^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

Formula (35) should be compared with Formula (23) which applies to the homogeneous slab. When EI is the same in the two formulas, and K in Formula (23) is zero, Formula (35) is seen to give only one-half the value of the critical loads found by Formula (23), that is, under those circumstances, elimination of the torsional resistance in a square slab cuts the buckling resistance in two. The resistance to a load in one direction only is still twice the critical load which would be found if the supporting edges parallel to the load were removed.

B.—Orthostatic Flexure.

The surface load, w, acting alone, gives a maximum bending moment, occurring at the center, equal to

$$M_{\max.} = 0.077\,w\,b^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (36)$$

(to be compared with $0.037\,wb^2$ in the square homogeneous slab, as given by Formula (28) with $\alpha = 1$). The method of deriving Formula (36) will be indicated in Part V.

C.—Heterostatic Action.

When $m = n = 1$ gives the smallest values of Q_a and Q_b in Formula (34), Formula (37) may be used for the moment at the center per unit width:

$$M'_{\max.} = 0.077\,w\,b^2\left(1 + 1.07\,\frac{P_a}{Q_a - P_a}\right) \quad \ldots\ldots\ldots (37)$$

(to be compared with Formula (32) applying to the homogeneous slab).

IV.—General Theory of Structural Actions in which the Stresses are not Proportional to the Loads, although Hooke's Law Applies in Each Element of the Structure, and although the Deformations are Small.

12.—The Energy Equation, the Loads, and the Parameters.—In the Introduction, Article 1, definitions were given of three general types of elastic action: Orthostatic or regular action, in which the stresses are proportional to the loads; astatic action in which pure buckling occurs; and heterostatic or mixed action. In the two latter types of action, the stresses are not, in general, proportional to the load. The two assumptions common to all cases considered are recalled, namely, that Hooke's law of proportionality of stresses and strains applies in each structural element, and that the deformations are small. It is now proposed to investigate some of the general features of astatic and heterostatic actions. The energy principle, or the principle of least action, is found to be particularly effective for this purpose. This principle makes it possible to express the conditions of equilibrium by one condition or equation — the energy equation. The following notation will be used:

Let U = total internal elastic energy stored in the structure by the deformation, or, the elastic potential energy of the structure. This quantity is called by many writers the resilience* of the structure, and this term will be used in this paper.

P = external load in the generalized sense, or "generalized force". P is a quantity which may represent one force or a group of forces acting on the structure. When all the forces in this group are increased by a certain proportion, this increase is represented by an increase of P by the same proportion. P, therefore, is a quantity measuring the intensity of load in the whole group of forces. The load, P, is the "generalized force" which was introduced by Lagrange in his general equations of dynamics.

δ = displacement in the direction of the load, P. If P is a single force, δ is the component of the linear displacement of the point where P is applied, in the direction of P. If P represents a group of forces, δ is such a quantity that $P\delta$ is the work done by the load, P, while the elastic displacements increase from zero to their final values, P being constant during this process. For example, if P is a torque (couple), δ is the angular rotation (in radians) of the structural part on which the couple is acting. If the load, P, consists of two forces each equal to P, acting against one another at the end points of a certain

* In Johnson's "Materials of Construction", 1919 edition, p. 38, resilience is defined as "the work which a body can do in springing back after a deforming force has been removed". The present use of the term is in accordance with this definition. See, also, A. E. H. Love, "Mathematical Theory of Elasticity", 1906 edition, p. 170, and J. A. Ewing, "Strength of Materials", 1906 edition, p. 15. There has been some disagreement as to the use of the term, resilience; for example, E. S. Andrews ("Strength of Materials", 1915, pp. 33, 272) uses the term in the sense of energy per unit volume.

distance, δ is the shortening of this distance. If the load, P, consists of two forces each equal to $\frac{1}{2}P$, acting against one another at the end points of a certain distance, δ is one-half the shortening of the distance, because only then could $P\delta$ be equal to the work of the load. If the load, P, consists of the individual forces, $P_1, P_2, \ldots\ldots P_n \ldots\ldots$, in the direction of which the displacements are, $\delta_1, \delta_2, \ldots\ldots \delta_n \ldots\ldots$, δ is found from the equation, $P\delta = \Sigma P_n \delta_n$. In Lagrange's dynamics, δ is the generalized displacement, or the change of a generalized co-ordinate.

$L =$ the difference between the internal energy or resilience of the structure and the work which is done by the external forces during the deformation, if the external forces remain constant during this process. That is, when P is the only load, $L = U - P\delta$. L may then be considered as the total potential energy of the structure and loads.

$u_1, u_2 \ldots\ldots u_m \ldots\ldots u_n \ldots\ldots =$ parameters of the structure which define the elastic displacements, or, in terms of Lagrange's dynamics, "generalized co-ordinates" of the structure. Unless otherwise stated, zero displacements correspond to $u_1 = u_2 \ldots\ldots = u_m \ldots\ldots u_n \ldots\ldots = 0$. Definite values assigned to each of the parameters will define completely the elastic changes of shape, that is, the displacements are functions of the parameters, u. In most cases, the number of parameters is infinite. In the case of an originally straight, incompressible, but flexible column, the constants in the Fourier series, expressing the deflections in terms of the distance along the column, may be used as parameters (compare Article 8) and they constitute a complete set. U and δ are functions of the parameters.

The general condition of equilibrium when P is the only load, may now be written:

$$L = U - P\delta = \pm \text{ min.} \quad \ldots\ldots\ldots\ldots\ldots\ldots (38)$$

The $\pm$ min. stands for "minimum or maximum or condition of zero derivatives". A minimum of L corresponds to a stable equilibrium, a maximum to an unstable equilibrium. As the cases of stable equilibrium, giving a minimum, are the more important—in orthostatic action this case will be found to be the only one possible—and as the definite conditions derived by differentiation of the equation are the same whether a maximum or a minimum occurs, the condition of equilibrium in the standard form may be written:

$$L = U - P\delta = \text{min.} \quad \ldots\ldots\ldots\ldots\ldots\ldots (39)$$

where the "minimum" on the right side is understood as a $\pm$ min., namely, usually a minimum, but, in special cases, a maximum. When the minimum occurs, Formula (39) expresses the "principle of least action". By differ-

entiating Formula (38) or Formula (39), with respect to the parameters, it will be found that:

$$\cdots\cdots\frac{\partial L}{\partial u_m} = 0 \cdots\cdots \frac{\partial L}{\partial u_n} = 0 \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots (40)$$

giving one equation for each parameter. The set of equations, Formula (40), is a complete equivalent of the energy equation, Formula (38) or Formula (39).

13.—The Internal Actions or Generalized Stresses, and the Elastic Potential Energy or Resilience.—The stresses at any one point measure the intensity of the internal elastic action. The stresses, however, are not the only quantities which can be used for this purpose; for example, in a beam which is bent by transverse forces only, the bending moment, M, is a measure of the intensity of action in a longitudinal element of length, ds, enclosed between two consecutive cross-sections. When EI is the product of the modulus of elasticity and the moment of inertia of the cross-section, $\frac{M^2\,ds}{2\,E\,I}$ is the internal energy or resilience of the element. If, in addition, there is an axial force, P, this force gives an additional stress uniformly distributed over the area, A, of the cross-section, and creates in the same structural element an additional element of energy equal to $\frac{P^2\,ds}{2\,E\,A}$. Therefore, P is also a "quantity measuring internal action". Usually, in beams and columns, the influence of the shearing stresses on the deformations is negligible. That is, the bending moments, M, together with the axial load, P, determine completely the internal energy or resilience of the column. M and P, therefore, may be called stresses in the generalized sense. In the general case, the action of a structure may be described in terms of some set of "internal actions" or "generalized stresses", R, which have such properties that the element of energy is written $\frac{1}{2}\,r\,R^2\,ds$, in which r is a function of the location and s measures "extension of the structure". The total elastic potential energy or the resilience is then expressed:

$$U = \frac{1}{2}\int r\,R^2\,ds \cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots (41)$$

where the integration is to be extended over the whole structure, and is to include all the elements of energy. It is always possible to indicate quantities such as R, which give an energy expression in the Formula (41).* As in the

*Let dV = volume element of a homogeneous isotropic elastic solid;
X, Y, Z = normal stresses in the directions, x, y, z;
S_{yz}, S_{zx}, S_{xy} = the corresponding shearing stresses;
E = modulus of elasticity;
K = Poisson's ratio of lateral contraction to longitudinal elongation.
Then, the elastic potential energy of the solid may be expressed:

$$U = \frac{1}{2}\int \left[\frac{1}{E}(X^2+Y^2+Z^2) - \frac{2K}{E}(YZ+ZX+XY) + \frac{2(1+K)}{E}(S^2_{yz}+S^2_{zx}+S^2_{xy})\right] dV \cdots\cdots (41a)$$

case of the axially compressed beam, the same element, ds, may be included more than once in the integral of the resilience.

It will be assumed that the actions, R, are linear functions, and, unless otherwise stated, linear homogeneous functions of the parameters, $u_1, u_2 \ldots\ldots$ When only small deformations of the structure are considered, it is always possible to choose a set of parameters satisfying this condition; and when one set of such parameters has been found, this set may be replaced by any other set in which each parameter is a linear homogeneous function of the parameters of the first set. Formula (42) may then be written:

$$R = R_1 u_1 + R_2 u_2 + \ldots\ldots + R_m u_m \ldots\ldots + R_n u_n + \ldots\ldots \quad (42)$$

where $R_1 \ldots\ldots R_n \ldots\ldots$, are functions of the location, that is, functions of s. Substituting Formula (42) in Formula (41) the expression for the internal energy or resilience is found:

$$U = \left(\frac{1}{2}\right) \sum_m u^2_m \int r R^2_m \, ds + \sum\sum_{mn} u_m u_n \int r R_m R_n \, ds \ldots\ldots \quad (43)$$

where $m = 1, 2 \ldots\ldots, n = 1, 2, \ldots\ldots$, and $m \neq n$, and where the integrations are extended so as to include all elements of energy. The integrals in the summations may be considered as "constants of the structure", and will be denoted as follows:

$$U_m = \int r R^2_m \, ds; \; U_{mn} = \int r R_m R_n \, ds \ldots\ldots\ldots\ldots \quad (44)$$

The resilience is then expressed:

$$U = \frac{1}{2} \Sigma U_m u^2_m + \Sigma\Sigma U_{mn} u_m u_n \ldots\ldots\ldots\ldots\ldots\ldots \quad (45)$$

where $m \neq n$. It is noted that U is a quadric in the parameters (a quadric is defined as a homogeneous function of second degree).

The additional notation introduced is summarized here as follows:

Let R = generalized stress, or, quantity measuring internal action;

ds = dimension of the structural element;

r = function of the location, depending on the stiffness of the element in such a way that $\frac{1}{2} r R^2 \, ds$ is equal to the corresponding element of energy or resilience;

As Formula (41a) contains the products, YZ, ZX, and XY, the stresses X, Y, and Z cannot be used as R's in Formula (41), except when two of these stresses are zero. Formula (41a), however, may be written in the form, Formula (41), for example, as follows:

$$U = \frac{1}{2} \int \left[\frac{1-2K}{3E} (X+Y+Z)^2 + \frac{1+K}{2E} (X-Z)^2 + \frac{1+K}{6E} (X-2Y+Z)^2 + \frac{2(1+K)}{E} (S^2_{yz} + S^2_{zx} + S^2_{xy}) \right] d\,V = \frac{1}{2} \int (\Sigma r R^2) \, ds \ldots\ldots \quad (41b)$$

That is, Formula (41) may be used with the following set of generalized stresses, R, corresponding to the volume element, dV or ds:

$$R^{\mathrm{I}} = X + Y + Z; \; R^{\mathrm{II}} = X - Z; \; R^{\mathrm{III}} = X - 2Y + Z; \; R^{\mathrm{IV}} = S_{yz}; \; R^{\mathrm{V}} = S_{zx};$$

$$R^{\mathrm{VI}} = S_{xy} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \quad (41c)$$

$R_1, R_2 \ldots\ldots R_m \ldots\ldots$ = coefficients of the parameters in the linear expression of R. These coefficients are functions of the location;

$\ldots\ldots U_m \ldots\ldots U_{mn} \ldots$ = constants of the structure, which are coefficients in the quadric expressing the resilience.

14.—The Case of Orthostatic Action.—The energy equation, Formula (39), and its equivalent, Formula (40), give equations of the form:

$$\frac{\partial L}{\partial u_m} = \frac{\partial U}{\partial u_m} - P\frac{\partial \delta}{\partial u_m} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (46)$$

namely, one such equation for each parameter. Since U is a quadric in the parameters (Formula (45)), the derivatives, $\frac{\partial U}{\partial u_m}$, are linear homogeneous functions of the parameters. In orthostatic action, the stresses, and, therefore, the parameters, are linear functions of the load, hence, if P is to give orthostatic action, the derivatives, $\frac{\partial \delta}{\partial u_m}$, must be independent of the u's; that is, they must be constants; or, δ in orthostatic action is a linear function of the parameters. It is assumed, in accordance with the general rule which was adopted, that the state of zero stresses and zero deformations is represented by zero values of the parameters. Then δ is a linear homogeneous function of the parameters.

*15.—Astatic Action, Astatic Parameters, and the Theorem of Orthogonality.**—It is now assumed that P is a load which can produce astatic action. Let Q_m be a value of P at which buckling is possible; that is, Q_m is a "critical value" of P. When P becomes equal to Q_m, then the structure enters into a state of astatic elastic equilibrium, that is, an equilibrium maintained at constant load throughout a continuous range of configurations of the structure. The parameter, u_m, will be chosen in a manner which correlates it peculiarly with the buckling under the load, Q_m. Three configurations or shapes of the structure will be considered, which will be called Configurations Nos. 1, 2, and 3. Configurations Nos. 1 and 2 are selected among the shapes of the structure which occur in the process of buckling under the load, Q_m. The change of the structure from Shape No. 1 to Shape No. 2 will be represented by a certain set of changes in the stresses or generalized stresses. The change of each generalized stress, R, will be expressed as the product, $R_m u_m$, of a fixed chosen value, u_m, times a factor, R_m. One such factor, R_m, belongs to each stress which is represented. The whole set of changes of stresses is defined completely when the set of such factors, R_m, and the quantity, u_m, are given. Now, assume that the value of u_m is changed, and that each factor, R_m, is multiplied by the new value of u_m. The products define a set of changes of the stresses. When the changes are measured from the initial configuration, No. 1, the set of changes defines a possible shape of the structure. This shape will be recorded as Configuration No. 3.

* It might seem that a simpler definition of the "astatic parameter" than the one given here could be found. The apparent complication is due to the fact that the definition is to apply, not only to the simplest cases, but also to the cases described later as "double astatic equilibrium" (Article 16) and "mixed astatic action" (Article 23).

The changes of stresses (generalized stresses or internal actions) caused by the transformation from Shape No. 1 to Shape No. 3 are proportional to the corresponding changes which occur when the structure is transformed from Shape No. 1 to Shape No. 2. The ratio between the two sets of changes is the ratio of the corresponding values of u_m. The same ratio exists between the corresponding changes of internal actions in general, and of other quantities which, like the deflections in general, are linear functions of the stresses. In other words, when u_m is used as a common factor defining changes of stresses, the variation of u_m alone will define a range of variations of shape; or u_m, used as indicated, serves as a parameter of the structure. Introducing u_m as such, and summarizing the results, we have: The changes through Configurations Nos. 1, 2, and 3 may be defined by the variation of the parameter, u_m, while the remainder of the parameters retain the constant values which they have in Configuration No. 1. Configuration No. 1, the initial shape from which the changes are measured, is represented by $u_m = 0$.

The general equation of equilibrium, Formula (39), is again written:

$$L = U - P\delta = \text{min.}$$

U is a quadric in the parameters. δ is some function of the parameters, but not a linear function, because, in accordance with Article 14, a linear function would lead to orthostatic action. As $P = Q_m$ gives equilibrium throughout a continuous range of variations, it follows that δ must be a function which resembles U in some respects. It might be assumed, then, that δ is a quadratic function of the parameters, or, more exactly, that in expressing δ as a polynomial or power series, terms of higher than second degree in the parameters can be thrown away as negligible. In some cases, one may verify by inspection of the structure the statement that δ is such a function.

By the following reasoning, one may conclude that, in the general case, δ is expressed with sufficient approximation as such a quadratic function of the parameters. The function, δ, is an elastic displacement. By the assumption of rigidity made in the Introduction, the displacements are small, and they may be considered as infinitesimal quantities when compared with the main dimensions of the structure, or, the displacements may be considered as small increments to the dimensions. They can be expressed in terms of the parameters by Taylor expansions. As the increments are small, the prevailing condition, special displacements being excepted, will be that in these expansions the terms of second and higher degree are negligible when compared with the linear terms. Such displacements, therefore, are expressed with sufficient approximation as linear functions of the parameters. In the special, exceptional case of the displacement, δ, in the direction of an astatic load, P, and in some related cases, it is not possible to throw away all terms of higher than first degree in the parameters. It follows from the usual properties of expansions in the Taylor series that, in such cases, it can be expected, and it will be true in general, that a sufficient approximation is obtained by including the terms of second degree in the parameters, neglecting terms of higher degrees. On this ground, it may be assumed that δ in Formula (39), in the case of astatic action, can be expressed sufficiently exactly as a quadratic

function of the parameters. In addition, however, as will be shown later, a criterion may be found for the correctness of this assumption in the very fact that astatic equilibria are known to exist; this knowledge may have been derived from other analyses or from tests.

When both U and δ are quadratic functions of the parameters, it follows that the formulas, derived by differentiating the energy equation, Formula (39), are linear in the parameters. That is, Formulas (40),

$$\dots \frac{\delta L}{\delta u_m} = 0 \dots \qquad \frac{\delta L}{\delta u_n} = 0 \dots$$

are linear in $\dots u_m \dots u_n \dots$ also in this case of astatic action. When $P = Q_m$, the set of Formulas (40) is satisfied by the sets of values of the parameters which correspond to Configurations Nos. 1 and 2, both of which belong to the astatic equilibrium under the load, Q_m. That is, the set of Formulas (40) is satisfied by two different values of u_m, namely, $u_m = 0$, corresponding to Configuration No. 1, and u_m equal to the first chosen finite value, corresponding to Configuration No. 2. The remainder of the parameters are the same in the two cases. It follows that, in Formulas (40), all coefficients to u_m vanish when $P = Q_m$. Formulas (40), however, will be satisfied by all values of u_m as long as the remainder of the parameters are as shown in Configuration No. 1. That is, the whole range of variations of shape—defined by u_m equals any value, all other parameters being equal to definite values, namely, their values in Configuration No. 1—represents a state of astatic equilibrium produced under the critical load, Q_m. This range contains as possible cases Configurations Nos. 1, 2, and 3.

We shall call u_m an astatic parameter. An astatic parameter is, therefore, by definition, a parameter which by its own variation, while the remainder of the parameters remain constant, defines the various stages of a state of astatic equilibrium.

As an example, take the case of a hinged-end column, of length, l, with constant cross-section, with a stiffness factor, EI, and with axial loads at the ends only. At the critical end load, $Q_m = \frac{\pi^2 m^2 EI}{l^2}$, an astatic equilibrium exists in which the deflected curve consists of m half waves. When x equals the distance from one end, the deflections in this buckling can be expressed as $y = u_m \sin \frac{m\pi x}{l}$, in which u_m may take any value. A change of u_m in this expression defines proportional changes of all stresses, curvatures, and transverse deflections. It follows that u_m, or any quantity proportional to it, can be used as an astatic parameter. In the general case of flexure, under the influence of an end load combined with transverse loads, the deflections can be expressed as $y = \Sigma u_n \sin \left(\frac{n\pi x}{l}\right)$, where $n = 1, 2 \dots m \dots$, etc. Evidently, the whole set of coefficients, $u_1 \dots u_m$, can be used as parameters, and they will all be astatic parameters. By introducing in addition to $u_1 \dots u_m \dots$, a parameter which measures the axial shortening of the column, one obtains a complete set of parameters in terms of which any

possible variation of shape can be described. It follows that the astatic equilibrium under the load, Q_m, is represented by u_m, being indefinite, equal to any value, other parameters being equal to definite values, namely, some finite value for the parameter measuring the axial shortening, and the remainder being equal to zero.

The general case is now considered again. The energy Formula (39):

$$L = U - P\delta = \text{min.}$$

will be used. It has been shown that when δ is known to be quadratic, two configurations, belonging to an astatic equilibrium, determine a corresponding astatic parameter. In the discussion which follows, we may abandon temporarily the assumption that δ is known beforehand to be a function of not higher than second degree in the parameters, even though this assumption is known to represent the general case. It will be assumed only that an astatic equilibrium is known to exist, and that a corresponding parameter, u_m, exists, which is an astatic parameter in the sense of the definition just given; that is, the variation of u_m, while the rest of the parameters remain constant, represents an astatic equilibrium produced under a critical load, say, $P = Q_m$. In this astatic equilibrium, it is found, as usual, that all the first partial derivatives of L with respect to the parameters must vanish. Moreover, since u_m can vary through a continuous range of values without disturbing the condition of minimum, it follows that, also, all second and higher derivatives of L in which differentiation with respect to the astatic parameter, u_m, occurs are zero. Hence, if u_n is any other parameter, we have, when $P = Q_m$:

$$\frac{\partial^2 L}{\partial u_m^2} = 0, \qquad \frac{\partial^2 L}{\partial u_m \partial u_n} = 0, \quad \ldots\ldots\ldots\ldots\ldots (47)$$

Now, assume that also u_n is an astatic parameter, and that its corresponding critical astatic load is Q_n; that is, u_n equals any value, other parameters being equal to definite values, represents an astatic equilibrium in which $P = Q_n$ is the load. Similar to Formula (47), we have then, when $P = Q_n$:

$$\frac{\partial^2 L}{\partial u_n^2} = 0, \qquad \frac{\partial^2 L}{\partial u_m \partial u_n} = 0, \quad \ldots\ldots\ldots\ldots\ldots (48)$$

The resilience quadric may be written in the form:

$$U = \frac{1}{2} U_m u_m^2 + \frac{1}{2} U_n u_n^2 + U_{mn} u_m u_n + \bar{U} \ldots\ldots\ldots (49)$$

where U_m, U_n, and U_{mn} are constants and where $\bar{U}$ is a function which has no terms containing u_m^2, u_n^2, or $u_m u_n$. It follows, from the relative position of U and δ in the energy equation and from the fact that all the partial derivatives of L with respect to u_m and u_n must vanish, that δ may be written in the form:

$$\delta = \frac{1}{2} \delta_m u_m^2 + \frac{1}{2} \delta_n u_n^2 + \delta_{mn} u_m u_n + \bar{\delta} \ldots\ldots\ldots\ldots (50)$$

where δ_m, δ_n, and δ_{mn} are constants, and where $\bar{\delta}$ is a function in which terms containing u_m^2, u_n^2, $u_m u_n$, or products of higher degree in u_m and u_n, do not exist.

Substituting Formulas (49) and (50) in the expression, $L = U - P\delta$, and differentiating in accordance with Formula (47), we find:

$$U_m - Q_m \delta_m = 0 \quad \ldots\ldots(51)$$

$$U_{mn} - Q_m \delta_{mn} = 0 \quad \ldots\ldots(52)$$

In the same manner, differentiating according to Formula (48), we find:

$$U_n - Q_n \delta_n = 0 \quad \ldots\ldots(53)$$

$$U_{mn} - Q_n \delta_{mn} = 0 \quad \ldots\ldots(54)$$

Formulas (51) and (53) may be written:

$$Q_m = \frac{U_m}{\delta_m}\,;\; Q_n = \frac{U_n}{\delta_n} \quad \ldots\ldots(55)$$

These simple formulas determine the astatic loads in terms of the coefficients in the functions, U and δ.

It is assumed at present that the two critical astatic loads, Q_m and Q_n, are different. It follows that Formulas (52) and (54) can be satisfied only when

$$U_{mn} = \delta_{mn} = 0 \quad \ldots\ldots(56)$$

that is, the mixed terms in U and δ containing the product, $u_m u_n$, vanish when the two parameters correspond to different critical astatic loads.

Since by Formula (44),

$$U_{mn} = \int r R_m R_n \, ds$$

we have,

$$\int r R_m R_n ds = 0 \quad \ldots\ldots(57)$$

The vanishing of this integral represents an important property of the functions, R_m and R_n, namely, the property of orthogonality. Two functions, $\phi(x)$ and $\psi(x)$, are called orthogonal in a certain field when their product integrated over the field vanishes, that is, when $\int \phi(x)\, \psi(x)\, dx = 0$. If R_m is taken as the one function, R_n, as the other, and $rds = dx$, it is seen that Formula (57) expresses this property. When there is a whole set of orthogonal functions—as will usually be the case in astatic action—these functions become useful by their adaptability to expansions in series, particularly in problems relating to the structures in which the functions are generated. This result will be brought out by the theory of heterostatic action which follows later. The theorem expressed by Formula (57) will be referred to as the theorem of orthogonality.*

As an example, consider the case of an hinged-end column, of the length, l, with a constant stiffness factor, EI, and with $s = x =$ distance from one end. The bending moments will be used as a measure of internal action, R, that is, as

* Sets of orthogonal functions play an important part in the theory of integral equations, and, therefore, it would be expected that the subject treated here would furnish an example of application of that theory. As a matter of fact, various elements in the subject of integral equations will appear to be represented directly and physically in the problems treated. For instance, the sets of characteristic numbers, or auto-values, in the homogeneous integral equations are represented as proportional to the sets of astatic loads. Concerning the theory of integral equations, see, for example, E. T. Whittaker and G. N. Watson, "Modern Analysis", Second Edition, 1915, pp. 205 *et seq.*

generalized stresses. The bending moments in two different astatic actions may be expressed as:

$$M_m = C_m \sin \frac{m\pi x}{l}, \text{ and } M_n = C_n \sin \frac{n\pi x}{l}$$

where $m \neq n$. It is well known that with $m \neq n$,

$$\int_0^l \sin \frac{m\pi x}{l} \times \sin \frac{n\pi x}{l} \times dx = 0$$

that is, with $R_m = M_m$, $R_n = M_n$, and $r = \frac{1}{EI}$, Formula (57) is satisfied.

Formula (50) shows that the part of δ which depends on the astatic parameters, u_m and u_n, alone is a quadratic function. This property is seen readily to extend to any number of astatic parameters. If in some manner or other certain parameters are known to be astatic, a corresponding part of δ will exist, which is quadratic in these parameters. Herein, is the criterion referred to previously by which, in many cases, the character of δ may be verified as a function of the parameters not higher than quadratic. This statement applies particularly to a group of cases, which will be shown to be important, namely, a group in which δ can be expressed in terms of astatic parameters, together with only one other parameter. The latter will be shown to enter into δ as a linear term; or, δ is in such cases a quadratic function of the set of parameters.

16.—Double Astatic Equilibrium.—In Article 15, the assumption was made that the two astatic loads, Q_m and Q_n, are different. The case will now be considered in which $Q_m = Q_n = Q_{mn}$. Formulas (51) to (54) are satisfied in this case when

$$Q_{mn} = \frac{U_m}{\delta_m} = \frac{U_n}{\delta_n} = \frac{U_{mn}}{\delta_{mn}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (58)$$

That is, in this special case, the mixed terms, containing u_m u_n, and having U_{mn} and δ_{mn} as coefficients, do not necessarily vanish, and the property of orthogonality is not necessarily found. Another result is that any combination of values of the two parameters, u_m and u_n, with the other parameters remaining constant, represents a possible equilibrium; that is, a double neutral or double astatic equilibrium occurs.

Some examples will illustrate this case: Consider a long cylindrical vertical column with such spherical bearings at the ends as to allow the ends to slope freely in any direction. At the lowest critical load given by the Euler formula, the column may buckle in any vertical plane through the original center line. Any such buckling may be found by superimposing a buckling curve in, say, the north-south plane on one in the east-west plane. Inversely, superposition of a buckling curve in the north-south plane on a buckling curve in the east-west plane, produced under the same critical load, leads to a possible buckling curve which will be contained in some vertical plane through the original center line. The equilibrium is a typical two-parametric astatic equilibrium, with two parameters assuming any values, while the remainder of the parameters have definite values. Another example is the thin-shelled circular cylinder carrying an outside pressure (Fig. 1 (*G*)). If the thickness and the material are uniform, the surface may buckle at the critical loads into

a wave line starting at any point. As both the maximum deflection and the starting point can vary, we have again a two-parametric astatic equilibrium. The complete set of buckling surfaces at that load can be found by superimposing the buckling waves starting at two definite points. A third example is the case of the rectangular slab carrying compressive loads along its edges. It was mentioned in Article 10 that, at certain combinations of the end load, the slab may buckle into two different types of waved surfaces and into any surface found by superposition of waves of these two types.

It is evident that triple or higher-multiple astatic equilibria may also be found. In the case of an hinged-end circular column with horizontal spring supports at the ends (compare Fig. 1 (*F*)), the springs may yield and the column may buckle in two different planes at the same critical load. This would be a triple astatic equilibrium.

17.—General Formulas in Simplified Case.—Assume that astatic action can be produced under the critical astatic loads, $Q_1, Q_2 \ldots\ldots Q_n \ldots\ldots$, and let $u_1, u_2 \ldots\ldots u_n \ldots\ldots$ be the corresponding set of astatic parameters, so that, for instance, the combination, $u_n =$ any value, other u's $= 0$, represents the astatic action produced when $P = Q_n$. The simplifying assumptions are made that this set of parameters is sufficient to define all the possible shapes of the structure, and that no two parameters correspond to the same Q; that is, all the Q's are different. For instance, if the axial shortenings can be neglected as being only of small influence, then the action of a slender straight column, flexible in one plane only, is described completely by an equation for deflections, of the form

$$y = \Sigma\, u_n \sin \frac{n \pi x}{l}$$

where x is the distance from one end. If the ends are hinged, and the stiffness factor, EI, is constant, then the u's in this expression are astatic parameters, and the combination, $u_n =$ any value, other u's $= 0$, corresponds to the critical astatic load,

$$Q_n = \frac{n^2 \pi^2 E I}{l^2}$$

In the general case, which will now be considered, the load is assumed to consist of two component parts which may vary independently: One part is denoted by P, and is an astatic load, which, acting alone, produces astatic equilibrium when it assumes any one of the critical values, $Q_1 \ldots\ldots Q_n \ldots$; the other part, W, is an orthostatic load, producing orthostatic action when acting alone. W cannot be a part of P. The combination of the two components, P and W, is a heterostatic load of a general type, producing heterostatic action. As before, δ is the displacement in the direction of P. In a similar manner, w will denote the displacement in the direction of the load, W, that is, Ww is the work of the load, W. The first object will be to find the parameters in the various possible cases. For the purpose of distinguishing between the cases, the particular values of the parameters occurring in the heterostatic action will be indicated by marking them with a prime, so that u'_n is the value of the parameter, u_n, in the heterostatic action. Without the prime,

u_n either represents the parameter as a variable quantity, or, when considered as a definite quantity, it denotes the particular value of the parameter occurring in the orthostatic action which is produced by W alone. When the parameters have been found, the various effects, such as deflections, bending moments, etc., that is, all generalized stresses, generalized strains, and generalized displacements, can be determined. These effects will be assumed to be linear homogeneous functions of the parameters. The "effects" will be denoted by F and F'. F will represent either "the effect in general", as a function of the parameters, or the particular value of the effect due to the orthostatic load, W, alone, while F' is the particular value of the effect in the heterostatic action. It is seen that the use of the prime is the same here as in the case of u_n and u_n'. Similarly, R' will denote the internal action in the heterostatic action, while R denotes either the internal action in general or the particular value of the internal action which occurs in the orthostatic action.

The notation introduced here is as follows:

Let
L = combined potential energy of structure and loads.
L = 0 when the displacement is zero.
U = resilience of the structure.
P = astatic component of the load.
W = orthostatic component of the load.
δ = displacement in the direction of the load, W, defined by Ww = work of W.
$Q_1, Q_2 \ldots Q_n \ldots$ = critical values of the astatic load, P.
$u_1 \ldots u_n \ldots$ = set of astatic parameters corresponding to the astatic load, P; in particular, when they are considered as definite quantities, they are the values of the parameters in the orthostatic action.
$u_1' \ldots u_n' \ldots$ = same parameters in the heterostatic action.
R = internal action, particularly in the orthostatic action.
R' = internal action in the heterostatic action.
ds = extension of structural element.
r = stiffness constant, so defined that $\frac{1}{2} rR^2 ds$ is an element of the resilience.
F = effect depending on the parameters, particularly the effect in the orthostatic action. F is a linear homogeneous function of the parameters.
F' = same effect in the heterostatic action.

The writer will show first how the parameters may be found in any given case, provided the internal actions are known. The intensity of internal action in any one element was expressed by Formula (42) as:

$$R = R_1 u_1 + \ldots\ldots R_m u_m + \ldots\ldots R_n u_n + \ldots\ldots$$

where $R_m \ldots R_n$ are functions of the location. u_n = any value, other u's being equal to zero, represents the astatic action produced by $P = Q_n$. Therefore, $R_n u_n$ is the internal action in the astatic action, Q_n, and the function,

R_n, has the particular significance of being the internal action in the astatic action, Q_n, when $u_n = 1$. For example, the bending moment, M, in Formula (11), which has reference to the general case of straight columns, may be chosen as a measure of the internal action, that is, in this case, $R = M$. The function, M_n, in Formulas (11) and (12), was defined as the bending moment in a possible buckling action, that is, we may write $R_n u_n = M_n$. Thus, Formula (11) appears as a special type of Formula (42). The general case is now considered again. Multiply Formula (42) by $rR_n ds$ and integrate so as to include all elements of energy. On account of the theorem of orthogonality, which states that $\int r R_m R_n \, d s = 0$, when $m \neq n$, all terms on the right side with an index different from n will vanish by the integration, and we find,

$$\int r R R_n \, d s = u_n \int r R_n^2 \, d s$$

or,

$$u_n = \frac{\int r R R_n \, d s}{\int r R_n^2 \, d s} \qquad (59)$$

The simplicity of Formula (59) shows the particular advantage of the sets of orthogonal functions generated in the astatic elastic actions. When the parameters have been found, their values may be substituted in the expressions for the various effects in the structure. Such effects are represented in general by a series of the form:

$$F = F_1 u_1 + \ldots\ldots + F_m u_m + \ldots\ldots + F_n u_n \qquad (60)$$

where $F_m \ldots\ldots F_n$ are functions depending on the location and on the type of the effect. The internal action, R, represents a special case of the general effect, F.

The energy equation will now be discussed. In the general case, in which both loads, P and W, are acting, the energy equation takes the form:

$$L = U - P\delta - Ww = \text{min.} \qquad (61)$$

the minimum here, as in Formula (39), being understood as a $\pm$ minimum. $P = 0$ gives orthostatic action, while $W = 0$ gives astatic action.

As all the critical loads, Q, are different, the quadric, U, does not contain any products of the parameters (compare Article 15), therefore, U may be written as a series,

$$U = \frac{1}{2} \Sigma U_n u_n^2 \qquad (62)$$

where the coefficients, U_n, are constants. It also follows that the quadratic function, δ, cannot contain products of the parameters. It will be shown a little later that δ does not contain any linear terms. δ is then a quadric similar to U and may be written:

$$\delta = \frac{1}{2} \Sigma \delta_n u_n^2 \qquad (63)$$

where the coefficients, δ_n, are constants. It was shown in Article 14 that the displacements in the direction of orthostatic loads are linear homogeneous functions of the parameters, therefore, w may be written:

$$w = \Sigma\, w_n u_n \ldots\ldots\ldots\

In a number of cases of orthostatic action, the parameters are found most conveniently by Formula (59). Since by Formula (44), $U_n = \int r\ R_n^2\ ds$, Formula (68) becomes, in fact, the same as Formula (59). The expression for w_n follows:

$$w_n = \int r\ R\ R_n\ d\ s \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (70)$$

Examples of the use of these methods in the analysis of orthostatic action may be found in Article 8. A part of the total resilience in the columns treated in Article 8, is due, in general, to the axial compression of the column, and this part would depend on some parameter other than the astatic parameters. A phase of the problem is involved here, which will be studied more closely in some of the subsequent articles. It will then be shown that such effects as the axial shortening do not change the applicability of the formulas and methods, just given, to the cases examined in Article 8. In the first case treated, that of hinged-end, straight columns, M_n in Formula (13) takes the place of $R_n u_n$. By choosing the coefficient, C_n, in Formula (13) as the parameter, u_n, it is found that $R_n = \sin \frac{n\ \pi\ x}{l}$. In this case, the factor, $r = \frac{1}{E\ I}$, is a constant which cancels when substituted in Formula (59). With $d\ s = d\ x$, it is found that,

$$\int R_n^2\ d\ s = \int_0^l \sin^2 \frac{n\ \pi\ x}{l}\ d\ x = \frac{l}{2}$$

The substitutions, $R = M$, $u_n = C_n$, transform Formula (59) into Formula (14), or

$$C_n = \frac{2}{l} \int_0^l M \sin \frac{n\ \pi\ x}{l}\ d\ x$$

Formula (14), therefore, may be interpreted as a special case of the general Formula (59). Integration of Formula (14) led to the series for M given shortly after Formula (14). This series exemplifies the expressions for R and F (Formulas (42) and (60)). Also, the other cases treated in Article 8 may be considered as examples of the more general theory.

C.—Heterostatic Action.

Both P and W are assumed to be different from zero. The energy equation, therefore, takes its general form, Formula (61). When U is taken from Formula (66), δ from Formula (63), and when the parameters are marked with a prime, the energy equation becomes:

$$L = \frac{1}{2} \Sigma\ (Q_n - P)\ \delta_n\ u'^2 - W\ \Sigma\ w_n\ u'_n = \min \ldots\ldots\ldots (71)$$

Differentiation with respect to the parameter, u'_n, gives:

$$\frac{\partial\ L}{\partial\ u'_n} = (Q_n - P)\ \delta_n\ u'_n - W\ w_n = 0 \ldots\ldots\ldots\ldots (72)$$

A comparison of Formula (72) with Formula (69) leads to the following expression for the parameter, u'_n, in the heterostatic action, in terms of the

value, u_n, of the same parameter in the corresponding orthostatic action in which the orthostatic load component, W, acts alone:

$$u'_n = \frac{Q_n}{Q_n - P} u_n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (73)$$

or,

$$u'_n = u_n + \frac{P}{Q_n - P} u_n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (74)$$

If u_n in Formula (73) or Formula (74) is considered as a constant, then the curve, (u'_n, P), in rectangular co-ordinates becomes a hyperbola with a horizontal asymptote, $P = Q_n$. The upper branch of this hyperbola represents an unstable equilibrium. If u_n is positive, then the lower branch of the hyperbola gives positive values, and the upper branch negative values, of u'_n. The reversal of the sign indicates that the equilibrium represented by points of the upper branch can be produced only when compensating deflections have been introduced first; that is, there must be deflections opposite those which are caused by W alone and which are represented by u_n.

By substituting Formula (74) in the series, Formula (60), which expresses the "effects" in the structure, and by using the prime to designate the action as heterostatic, the following formula will be found, which expresses the effect, F', in the heterostatic action in terms of the corresponding effect, F, in the orthostatic action produced by the orthostatic load component, W, acting alone:

$$F' = F + \Sigma \frac{P}{Q_n - P} F_n u_n \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

This formula furnishes a solution of the problem of heterostatic action as existing in a large group of cases. An important example of application is the general Formula (12) in Article 7, which was used extensively in Part II, and which expresses bending moments in combined column action and bending, namely,*

$$M' = M + \Sigma \frac{P}{Q_n - P} M_n$$

As referred to previously, a part of the resilience of a straight column is due to the axial shortening, but as has been mentioned in connection with an application of Formula (70), and as will be shown in the following articles, this condition does not interfere with the applicability of the general Formula (75) to the case represented by Formula (12). One derives Formula (12) from Formula (75), by taking the bending moments, M and M', as the "effects", F and F', in Formula (75), and by substituting the bending moment, M_n, which is produced in the buckling under the axial load, Q_n, for the effect, $F_n u_n$, which is produced in the general astatic action under the load, Q_n.

* Goupil in *Annales des Ponts et Chaussées*, 1912, V, p. 401, indicates a formula and a rule of computation which might be derived as another special case of Formula (75). The case is that of a circular ring with constant cross-section, or of a cylinder with constant thickness. The load consists of pressures from the inside or outside, distributed in any manner. The "effects" are the deflections, but it is also shown how the bending moments may be found. The formula is similar to Formulas (75) and (12). It is evident that Formula (75), in the form of Formula (12), applies not only to straight, but also to curved members. Goupil quotes this derivation as having been indicated in lectures by Marbec and Le Besnerais at l'Ecole du Génie Maritime. This derivation is based on the differential equation of flexure applying in the particular case, and use is made of the Fourier series.

18.—Independent Parameters.—We shall now leave the simplified case treated in Article 17 and consider a case of a general nature. Assume that P denotes any load acting on the structure, and that no other loads are applied. Then the energy equation takes the form of Formula (39), or,

$$L = U - P\delta = \text{min.}$$

Assume that the resilience, U, can be expressed:

$$U = \bar{U}\ (u_1 \ldots\ldots u_n \ldots\ldots) + T\ (t_1 \ldots\ldots t_i \ldots\ldots) \ldots\ldots (76)$$

where $\bar{U}$ is a quadric in $u_1 \ldots\ldots u_n \ldots\ldots$, and T a quadric in $t_1 \ldots\ldots t_i \ldots\ldots$ As $\bar{U}$ cannot be negative, neither U nor T can be negative. It is assumed that $T = 0$ only when $t_1 = \ldots\ldots = t_i = \ldots\ldots = 0$. The displacement, δ, in the direction, P, is in the general case a quadratic function of the parameters. Assume that δ depends on the u's only, or,

$$\delta = \delta\ (u_1 \ldots\ldots u_n \ldots\ldots)$$

Under these circumstances, the general energy equation, Formula (39), is equivalent to the two independent conditions combined, namely,

$$T = \text{min.} \ldots\ldots (77)$$

and,

$$L' = \bar{U} - P\delta = \text{min.} \ldots\ldots (78)$$

Under the assumptions made, the only solution of Formula (77) is $t_1 = \ldots\ldots = t_i = \ldots\ldots = 0$. Formula (78) is an energy equation of the usual type shown in Formula (39), but contains only the parameters, $u_1 \ldots\ldots u_n$. Under these conditions, the parameters, $t_1 \ldots\ldots t_i$, are "parameters independent of the load, P". If P is an astatic load, or the astatic component of a load of general type, the parameters, $t_1 \ldots\ldots t_i$, will be referred to simply as "independent parameters".

When P is an astatic load, the occurrence of independent parameters may be represented as a limiting case in which one or more of the coefficients, δ_m, δ_n, $\delta_{mn} \ldots$, in the expressions for δ, such as Formula (50) or Formula (63), become equal to zero without the vanishing of the corresponding coefficients in U. When u_m is an astatic parameter, the corresponding astatic load is expressed, in general, as $Q_m = \dfrac{U_m}{\delta_m}$ (Formula (55)). Hence, $\delta_m = 0$ represents the limiting case, $Q_m = \infty$, the case in which the astatic load, Q_m, has become infinite. In the same manner, $\delta_m = \delta_n = \delta_{mn} = 0$ represents the limiting case, $Q_m = Q_n = \infty$.

As an example, consider an hinged-end column which is originally vertical and is supported at the ends by two horizontal springs, as indicated in Fig. 1(F). A horizontal parallel motion of the column would not change the vertical distance between the ends, therefore, a parameter expressing such a variation of position is an independent parameter. When the two springs are equally stiff, this parameter can be measured in any state of deformations, as the sum of the horizontal displacements of the two ends, considered positive in the same direction. Another parameter which is measured by the difference of the horizontal deflections of the ends, is a regular astatic parameter. The

functions which represent the internal actions corresponding to those two parameters are easily shown to be orthogonal, as they should be, because one corresponds to an infinite, and the other to a finite, critical astatic load.

As another example, take a structure consisting of a column plus some independent structure. The parameters defining the variations in this independent structure are independent parameters with reference to the axial load on the column.

19.—The Orthostatic Parameter in Pure Astatic Action, and the Vanishing of Certain Constants.—Consider the vertical hinged-end column, of a length, l, with a uniform stiffness factor, EI, an area of cross-section, A, and with the axial loads transferred at the ends only. It was pointed out in Article 17 that the coefficients, u_n, in the expression for the deflections, $y = \Sigma\, u_n \sin \frac{n \pi x}{l}$, combined with one parameter measuring the axial shortening, would form a complete set of parameters in terms of which any possible type of deformation could be expressed. At the beginning of Article 17, it was stated that if the column is very slender, the axial shortening would have only a negligible influence on the total energy variations, and in that case the column would belong directly in the simplified class treated in Article 17. It was also stated—without proof—that certain applications of the formulas derived could be made even if an appreciable amount of energy is consumed by the axial shortening. The questions involved here will now be investigated.

Let v denote the parameter which measures the axial shortening; that is, v is a quantity proportional to the uniformly distributed axial shortening due to the direct compressive stress. When the terms depending on v have been added, the resilience, U, and the displacement, δ, in the direction of P, are expressed as follows:

$$U = \frac{1}{2} \Sigma\, U_n u_n^2 + \frac{1}{2} V v^2$$

$$\delta = \frac{1}{2} \Sigma\, \delta_n u_n^2 + \gamma v$$

in which V and γ are constants. The energy equation, $L = U - P\delta = \text{min.}$, gives, in this case, $\frac{\partial L}{\partial v} = V v - P\gamma = 0$, or, $v = \frac{P\gamma}{V}$, that is, v is proportional to the load.

Also, in other cases of astatic action, there is generally one variation of shape which is directly proportional to the load and which can be expressed by a parameter such as v. In the special solution, in which all the astatic parameters are zero, the deformations are, as a whole, proportional to v and thereby to the astatic load, P. Such a parameter, which measures that particular variation in the astatic action which is proportional to the load, will be called an orthostatic parameter.

A general case will be considered in which the variations of the structure can be expressed in terms of the following three kinds of parameters: Astatic parameters, $u_1 \ldots\ldots u_n \ldots\ldots$; the orthostatic parameter, v; and the independent parameters, $t_1 \ldots\ldots t_i \ldots\ldots$ When these parameters are sufficient to define all the possible variations of the structure, the astatic action produced by the astatic

load, P, corresponding to the parameters, $u_1 \ldots\ldots u_n$, will be called a pure astatic action. This action is characterized by the condition that $P = Q_n$ gives as a possible solution, $u_n =$ any value, v being proportional to Q_n and all the other parameters being zero.

The energy equation, Formula (39), will be used again,

$$L = U - P\delta = \text{min.}$$

In this case, we write:

$$U = \overline{U}(u_1 \ldots\ldots u_n \ldots) + \frac{1}{2} V v^2 + v \Sigma V_n u_n + T(t_1 \ldots\ldots t_i \ldots\ldots) \ldots\ldots (79)$$

and,

$$\delta = \overline{\delta}(u_1 \ldots\ldots u_n \ldots) + \Sigma \varepsilon_n u_n + \gamma v + v \Sigma \gamma_n u_n \ldots\ldots\ldots (80)$$

in which $\overline{U}$, T, and $\overline{\delta}$ are quadrics, while V, V_n, ε_n, γ, and γ_n are constants. Differentiation gives:

$$\frac{\partial L}{\partial u_n} = \left(\frac{\partial \overline{U}}{\partial u_n} - P \frac{\partial \overline{\delta}}{\partial u_n}\right) - P \varepsilon_n + (V_n - P \gamma_n) v = 0 \ldots\ldots (81)$$

and,

$$\frac{\partial L}{\partial v} = (V v - P \gamma) + \Sigma (V_n - P \gamma_n) u_n = 0 \ldots\ldots\ldots (82)$$

Since $u_1 = \ldots\ldots u_n = \ldots\ldots = 0$ is a possible solution at any value of P, Formula (82) gives $V v - P \gamma = 0$, or,

$$v = \frac{P \gamma}{V} \ldots\ldots\ldots (83)$$

$P = Q_n$ gives as a possible solution $u_n =$ any value, other u's being zero, therefore, Formula (82) gives $V_n = Q_n \gamma_n$. All u's being equal to zero makes $\frac{\partial \overline{U}}{\partial u_n} - P \frac{\partial \overline{\delta}}{\partial u_n} = 0$, that is, in this solution the first term in Formula (81) vanishes. When, especially, $P = Q_n$, the last term in Formula (81) vanishes, therefore, $Q_n \varepsilon_n = 0$, that is,

$$\varepsilon_1 = \ldots\ldots = \varepsilon_n = \ldots\ldots = 0 \ldots\ldots\ldots (84)$$

Finally, the combination, $u_1 = \ldots\ldots u_n = \ldots\ldots = 0$, v being finite, $P \neq Q_n$, gives, on account of Formula (81):

$$V_n = \gamma_n = 0 \ldots\ldots\ldots (85)$$

Formulas (84) and (85) express the result that, in the case of pure astatic action, the linear terms in the astatic parameters vanish in the expression for δ, and the mixed terms containing products of the orthostatic and the astatic parameters vanish in the expression for U and δ.

20.—The Parameters and the Energy Equation in the General Case.— A case will now be treated which is more general than the simplified one analyzed in Article 17. As in Article 17, the load will be assumed to consist of two component parts: $W =$ orthostatic component of the load, and $P =$ astatic component of the load.

As before, it is assumed that the series, $Q_1, Q_2 \ldots\ldots Q_n \ldots\ldots$, is the series of different critical values of the astatic load, P. It is also assumed that some

finite number of astatic parameters corresponds to each critical load, so that the complete set of astatic parameters can be written:

$u_{1a}, u_{1b} \ldots\ldots u_{1k}, \ldots\ldots$ corresponding to Q_1;
$u_{2a}, u_{2b} \ldots\ldots u_{2k}, \ldots\ldots$ corresponding to Q_2;
$\ldots\ldots$
$u_{na}, u_{nb} \ldots\ldots u_{nk}, \ldots\ldots$ corresponding to Q_n;
$\ldots\ldots$

In addition, there are the following special parameters: v = orthostatic parameter; and $t_1, t_2 \ldots\ldots t_i \ldots\ldots$ = independent parameters.

It is assumed that these parameters are sufficient to determine the possible variations of shape of the structure. It follows then from the definition given in Article 19 that the buckling under the influence of P is a pure astatic action. A prime will be used again to denote the particular value of a parameter in the heterostatic action; so that we have, for instance, u'_{nk} = the particular value of the parameter, u_{nk}, in the heterostatic action. The notation, $\delta, w, R, R', ds, r, F$, and F', is the same as that given in Article 16.

The energy equation takes again the form of Formula (61), or,

$$L = U - P\delta - Ww = \text{min.}$$

When writing expressions for U and δ use will be made of the theorem of the vanishing of the mixed terms which contain the products of two astatic parameters that belong to different critical loads (Article 15). The coefficients of certain other terms also vanish, as was indicated in Article 19. The result is that the resilience, U, and the displacements, δ and w, can be expressed as follows:

$$U = \Sigma U^{(n)} + \frac{1}{2} Vv^2 + T(t_1, t_2 \ldots) \ldots\ldots (86)$$

$$\delta = \Sigma \delta^{(n)} + \gamma v \ldots\ldots (87)$$

$$w = \sum_n \sum_i w_{ni} u_{ni} + \bar{w} \ldots\ldots (88)$$

in which $U^{(n)}$ and $\delta^{(n)}$ are quadrics in the parameters, $u_{na} \ldots\ldots u_{ni} \ldots\ldots$, which belong to the critical load, Q_n, and in which,

V, γ, w_{ni} = constants;
T = quadric in the parameters, $t_1, t_2 \ldots\ldots$; and
w = linear function of $t_1, t_2 \ldots\ldots$, and v.

The quadric, $\delta^{(n)}$, may be written:

$$\delta^{(n)} = \frac{1}{2} \sum_i \delta_{ni} u_{ni}^2 + \Sigma \delta_{ni, nk} u_{ni} u_{nk} \ldots\ldots (89)$$

The relation, Formula (58), between the coefficients in U and δ applies to the coefficients in Formula (89), therefore, the quadric, $U^{(n)}$, can be written in the form:

$$U^{(n)} = Q_n \delta_n \ldots\ldots (90)$$

21.—Solution of the Energy Equation in the General Case.—

A.—Astatic Action.

Assume $P = Q_n$, $W = 0$, then the energy equation, Formula (61), is satisfied when $u_{na}, u_{nb} \ldots\ldots u_{ni} \ldots\ldots$ assume any values, and $v = P \frac{\gamma}{V}$ (Formula 83), all other parameters being equal to zero.

B.—Orthostatic Action.

$P = 0$ puts the energy equation in the form $L = U - Ww = \min$. Differentiation then gives a set of equations of the type:

$$\frac{\partial L}{\partial u_{ni}} = Q_n \frac{\partial \delta^{(n)}}{\partial u_{ni}} - W w_{ni} = 0 \ldots\ldots\ldots\ldots\ldots\ldots (91)$$

or, if Formula (89) is used:

$$Q_n (\delta_{na \cdot ni} u_{na} + \delta_{nb \cdot ni} u_{nb} + \ldots\ldots + \delta_{ni} u_{ni} + \ldots\ldots) = W w_{ni} \ldots\ldots (92)$$

By making $i = 1, 2, 3 \ldots\ldots$, a set of equations similar to Formula (92) is obtained. One such set of linear equations is derived for each critical load, and thereby sufficient relations are found for the determination of all the astatic parameters. In the special case in which there is only one astatic parameter, u_n, corresponding to Q_n, the quadric, $\delta^{(n)}$, is reduced to the form:

$$\delta^{(n)} = \frac{1}{2} \delta_n u^2_n$$

whereby Formula (92) is reduced to the following special form, which is equivalent to Formula (69):

$$Q_n \delta_n u_n = W w_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (93)$$

The orthostatic parameter, v, and the independent parameters, $t_1, t_2 \ldots\ldots$, are found in a similar manner from equations of the form:

$$\frac{\partial L}{\partial v} = 0, \frac{\partial L}{\partial t_1} = 0, \frac{\partial L}{\partial t_2} = 0, \text{etc.}$$

C.—Heterostatic Action.

In this case, the astatic parameters are denoted with a prime, as, for example, u'_{ni}. By substituting Formulas (86), (87), (88), and (90), in the energy equation, $L = U - P\delta - Ww = \min.$, and differentiating with respect to the astatic parameters, equations of the following type are found:

$$\frac{\partial L}{\partial u'_{ni}} = (Q_n - P) \frac{\partial \delta^{(n)}}{\partial u'_{ni}} - W w_{ni} = 0 \ldots\ldots\ldots\ldots (94)$$

These equations are linear. By the substitution of Formula (89) for $\delta^{(n)}$, Formula (94) is transformed into:

$$(Q_n - P) (\delta_{na \cdot ni} u'_{na} + \delta_{nb \cdot ni} u'_{nb} + \ldots\ldots + \delta_{ni} u'_{ni} + \ldots\ldots) = W w_{ni} \ldots (95)$$

A set of equations like Formula (95) is obtained by making $i = 1, 2, 3 \ldots\ldots$ One such set of equations belongs to each astatic load. By comparing Formula (95) with Formula (92), the following general relation is found between the values, u_{ni}, of the parameters in the orthostatic action produced by W alone,

and the values, u'_{ni}, of the same parameters in the heterostatic action produced by P and W together:

$$u'_{ni} = \frac{Q_n}{Q_n - P} u_{ni} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (96)$$

or,

$$u'_{ni} = u_{ni} + \frac{P}{Q_n - P} u_{ni} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (97)$$

These formulas are actually the same as Formulas (73) and (74), which were derived for the simplified case. That is, Formulas (73) and (74) can be applied generally.

The orthostatic parameter in the astatic action was found to be $v = \frac{P\gamma}{V}$ (Formula (83)). Assume that the orthostatic action gives the value, v_0. Since v enters only in linear terms in δ and w (Formulas (87) and (88)), the value, v', of the orthostatic parameter in the heterostatic action can be found by adding the values in the corresponding astatic and orthostatic actions, that is,

$$v' = \frac{P\gamma}{V} + v_0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (98)$$

The derivatives, $\frac{\partial L}{\partial t_1}, \frac{\partial L}{\partial t_2}$, etc., are the same as those in the orthostatic action, hence the independent parameters, $t_1, t_2, \ldots\ldots$, are the same in the heterostatic action as in the corresponding orthostatic action.

Now, consider some effect, F. The particular value of F in the heterostatic action is denoted by F'. Assume that F can be expressed as,

$$F = \Sigma F^{(n)} + F_0 v + \overline{F}(t_1, t_2 \cdots) \quad \ldots\ldots\ldots\ldots\ldots (99)$$

where F_0 is a constant and where $F^{(n)}$ is a linear homogeneous function of the astatic parameters belonging to Q_n. That is, $F^{(n)}$ can be written:

$$F^{(n)} = F_{na} u_{na} + F_{nb} u_{nb} + \cdots + F_{ni} u_{ni} + \cdots\cdots\cdots (100)$$

We now introduce the particular values, $\ldots u'_{ni}$ and v', given by Formulas (97) and (98), in Formulas (99) and (100), and we find thereby the value, F', of the effect, F, in the heterostatic action. This value, F', is then expressed as follows in terms of the corresponding values, F, u_{ni} and $F^{(n)}$, which occur in the orthostatic action:

$$F' = F + \sum_n \frac{P}{Q_n - P} \sum_i F_{ni} u_{ni} + P \frac{F_0 \gamma}{V} \quad \ldots\ldots\ldots\ldots (101)$$

or,

$$F' = F + \sum_n \frac{P}{Q_n - P} F^{(n)} + P \frac{F_0 \gamma}{V} \quad \ldots\ldots\ldots\ldots (102)$$

Formulas (101) and (102) express the effect in the heterostatic action in a case of a most general character, namely, the general case in which the heterostatic load can be resolved into one orthostatic component, W, and one component, P, giving pure astatic action. Like F and u_n in Formula (75) (which is the general formula derived in the simplified case), F, u_n, and $F^{(n)}$ in Formulas (101) and (102) are values belonging to the "corresponding ortho-

static action" produced when $P = 0$. Formula (75) may be derived as the special case of Formula (102) in which $F^{(n)} = F_n\, u_n$ and $F_0\, \gamma = 0$. The general Formula (12) used in Part II is seen readily to be the special case of Formula (102), in which the "effects", F, F', and $F^{(n)}$, are the bending moments, M, M', and M_n, respectively. F_0 is zero in that special case. These considerations also prove finally that the applications made in Article 17 to straight columns are valid whether or not the axial shortening is appreciable.

22.—Determination of the Parameters in the General Case, When the Internal Actions Are Known.—The intensity of internal action, the generalized stress, R, may be considered as an "effect", and may be expressed in the same manner as F in Formula (99). We write then:

$$R = \Sigma\, R^{(n)} + R_0\, v + R\,(t_1, t_2 \cdots) \quad \ldots\ldots\ldots\ldots\ldots\ldots (103)$$

in which,

$$R^{(n)} = R_{na}\, u_{na} + R_{nb}\, u_{nb} + \cdots + R_{ni}\, u_{ni} + \ldots\ldots\ldots\ldots\ldots\ldots (104)$$

The energy of the element, ds, is $\frac{1}{2}\, rR^2 ds$, so that the total resilience is $U = \frac{1}{2} \int rR^2 ds$ (Formula (41)). U is a quadric in the parameters, but has no terms containing products of the following types: $u_{ni} u_{mk}$, where $n \neq m$; $u_{ni}\, v$; $u_{ni}\, t_k$; $v t_k$. This property of u is expressed in Formula (86), which omits all such terms. It follows that the property of orthogonality, proved in Article 15 with reference to two astatic parameters, is extended so as to include the following relations:

$$\int rR_{ni}\, R_{mk}\, ds = 0 \quad (m \neq n, \text{ compare Formula (57)}) \ldots\ldots\ldots (105)$$

$$\int rR_{ni}\, R_0\, ds = 0\,; \quad \int rR_{ni}\, \bar{R} ds = 0\,; \quad \int rR_0\, \bar{R} ds = 0 \ldots\ldots (106)$$

Multiplying Formula (103) by $rR_{ni}\, ds$ and integrating so as to include all elements of energy, thereby making use of Formulas (105) and (106), we find,

$$\int r\, R\, R_{ni}\, ds = \int r\, R^{(n)}\, R_{ni}\, ds \quad \ldots\ldots\ldots\ldots\ldots\ldots (107)$$

or,

$$\int r\, R\, R_{ni}\, ds = u_{na} \int r\, R_{na}\, R_{ni}\, ds + u_{nb} \int r\, R_{nb}\, R_{ni}\, ds + \ldots\ldots$$
$$+ u_{ni} \int r\, {R_{ni}}^2\, ds + \ldots\ldots\ldots\ldots\ldots\ldots (108)$$

The latter equation (Formula (108)) is one of a set which may be written:

$$\left.\begin{aligned} u_{na} \int r\, {R_{na}}^2\, ds + u_{nb} \int r\, R_{nb}\, R_{na}\, ds + \ldots\ldots \\ + u_{ni} \int r\, R_{ni}\, R_{na}\, ds + \ldots\ldots = \int rR\, R_{na}\, ds \\ u_{na} \int r\, R_{na}\, R_{nb}\, ds + u_{nb} \int r\, {R_{nb}}^2\, ds + \ldots\ldots \\ + u_{ni} \int r\, R_{ni}\, R_{nb}\, ds + \ldots\ldots = \int rR\, R_{nb}\, ds \\ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \end{aligned}\right\} \quad (109)$$

This set contains one equation for each of the parameters, u_{na}, u_{nb}, ... u_{nt} ..., which belong to the critical load, Q_n. One set of such equations can be derived for each different critical load, and thereby a number of equations are found, which are sufficient for the determination of all the astatic parameters. A very important special case is that in which u_{na} is the only parameter belonging to the critical load, Q_n. In that case the set, Formula (109), is reduced to one equation, which may be written:

$$u_{na} = \int \frac{r\, R\, R_{na}\, ds}{r\, R_{na}^{\,2}\, ds} \qquad \text{(110)}$$

The index, n, may be used in this special case instead of na. Then, Formula (110) becomes identical with Formula (59), which was derived for the simplified case in Article 17, in a very similar manner.

Formula (110) applies under special circumstances, even when there is more than one astatic parameter belonging to Q_n. It applies whenever the condition, $\int r\, R_{nb}\, R_{na}\, ds = \ldots = \int r\, R_{nt}\, R_{na}\, ds = \ldots = 0$, is satisfied. In such a case, the parameter, u_{na}, will be said to have been orthogonalized with respect to the other parameters in the group, $u_{nb} \ldots u_{nt}$. It is always possible, by a proper choice of the parameters in the group belonging to one critical load, to orthogonalize all the parameters in this group with respect to each other. This process is often facilitated by properties of symmetry of the structure. Take, for instance, the vertical hinged-end column with spherical bearings and with circular cross-section: Two astatic parameters will correspond to each critical load. Each such pair of parameters is orthogonalized by choosing the parameters so that they measure the amounts of buckling in two vertical planes perpendicular to one another.

The orthostatic parameter, v, is found in a similar way. Multiplying Formula (103) by $r\, R_0\, ds$, integrating, thereby using the properties of orthogonality expressed in Formula (106), and solving for v, we find an expression, similar to Formula (110), namely,

$$v = \int \frac{r\, R\, R_0\, d\, s}{r\, R_0^{\,2}\, d\, s} \qquad \text{(111)}$$

The independent parameters, t_1, t_2 ....., can be determined in the same manner as any group of astatic parameters. One finds a set of equations of the same form as that shown in Formula (109).

23.—Mixed Astatic Action.—We will consider again the general formula for heterostatic action, namely,

$$F' = F + \sum_n \frac{P}{Q_n - P}\, F^{(n)} + P\, \frac{F_0\, \gamma}{V} \qquad \text{(102)}$$

where $F^{(n)} = \Sigma\, F_{nt}\, u_{nt}$. In the special case, $P = Q_n$, the effect, F', would generally become infinite, except when $F^{(n)} = 0$, in which particular case, Formula (102) indicates F' as indefinite. This consideration suggests that P combined with special types of the orthostatic load, W, may cause astatic actions which differ from the pure astatic action produced by P acting alone, but which have, nevertheless, some of the characteristic features of pure buckling. The most important of these features is that of the indefinite dis-

placements at constant values of the load. The possibility of such "mixed astatic actions", produced under the combined influence of a pure astatic load and an orthostatic load, will now be examined.

Consider Formula (95): It is one of a set belonging to Q_n. The set is completed by exchanging the indices, na, nb....., respectively, for ni. It is assumed that,

$$w_{na} = w_{nb} = \ldots\ldots = w_{ni} = \ldots\ldots = 0.$$

Then the set of Formulas (95) is solved as follows:

When $P \neq Q_n$, $u'_{na} = u'_{nb} = \ldots\ldots\ u'_{ni} = \ldots\ldots = 0$;
When $P = Q_n$, $u'_{na}, u'_{nb} \ldots\ldots\ u'_{ni} = \ldots\ldots =$ any values.

This solution satisfies Formula (94), and when the other parameters have been found by the methods indicated in Article 21, by using, for instance, Formulas (97) and (98), the combined solution will satisfy the general energy equation, Formula (61). The conclusion is that $P = Q_n$ produces astatic action when combined with W, provided the coefficients, $w_{na}\ldots\ldots w_{ni}\ldots\ldots$, vanish. On account of Formula (92), this condition can also be expressed as follows: Astatic action is possible when the values, u_{na}, $u_{nb}\ldots\ldots u_{ni}\ldots\ldots$, as determined in the orthostatic action produced by W alone, are zero.

A whole series of special critical loads, Q_n, Q_n', Q_n''....., forming a part of the complete series of critical values of P, may give astatic action, although the astatic load is combined with the orthostatic load, W. Now, assume that W varies proportionally to P. In that case, the combination, P, W, can be considered as one load, the intensity of which is measured by P. As it produces astatic action when the intensity reaches the critical values, Q_n, Q_n', Q_n''....., the heterostatic load, P, W, may be considered as an astatic load. Let u_{mk} be some astatic parameter which W, acting alone, causes to be different from zero, and let the value, u_{mk}, be the particular value produced by W alone; then, Formula (97) would give the corresponding value of the parameter produced by the combination, P, W, namely,

$$u'_{mk} = u_{mk} + \frac{P}{Q_m - P} u_{mk}$$

u_{mk} is proportional to W, which is assumed to be proportional to P. It follows that u'_{mk} is neither constantly zero, nor proportional to P, and therein lies a principal difference between the pure astatic action produced by P, and astatic action produced by the load, P, W. It is the latter type of astatic action which is designated as "mixed astatic action". This discussion may be summarized as follows: The load, P, W, in which W is proportional to P, may produce astatic action at a series of critical values of P. When one or more of the astatic parameters becomes different from zero, under the influence of W, then stresses and other effects in the structure are neither all zero, nor proportional to the load, even when the load is different from any critical value. In that case, the action is a mixed astatic action, to be distinguished from the pure astatic action in which, as long as the load is different from its critical values, the effects are either zero or proportional to the load.

In the case analyzed, u_{na}, $u_{nb}\ldots\ldots u_{ni}\ldots\ldots$ are astatic parameters, not only with reference to the load, P, but also with reference to the astatic load, P, W.

Yet, u_{mk} can be classified neither as an astatic, an orthostatic, nor as an independent parameter. The only case in which the effects in a structure can be described completely in terms of astatic parameters, one orthostatic parameter, and independent parameters, with reference to a certain load, is that in which this load produces pure astatic action. In most cases, it is possible to conclude from the nature of the structure and from the nature of the load whether a certain astatic action is a pure or a mixed action. If it is a mixed astatic action, then, in order to make the general Formulas (101) and (102) applicable, the load should be resolved into two components, one, P, giving pure astatic action, the other, W, giving orthostatic action.

As an example, consider a hinged-end column with the load, P, transferred at the ends with equal but opposite eccentricities, $\pm e$. The case was treated in Article 9. Astatic equilibria occur when $P = \frac{n^2 \pi^2 E I}{l^2}$, where $E I =$ the stiffness factor, $l =$ the length, and $n = 1, 3, 5 \ldots\ldots$ Between these critical loads, the stresses, deflections, and other actions do not increase proportionally to the load, except at special points. The case may be classified as heterostatic action or as mixed astatic action. The load may be resolved into an astatic component giving pure astatic action, namely, a central end load, P, and an orthostatic component, namely, the end moments, Pe, both clockwise, or both anti-clockwise. If the same column is loaded by a central axial end load and, at the same time, by a symmetrical transverse load, then astatic equilibria occur at $P = \frac{n^2 \pi^2 E I}{l^2}$, with $n = 2, 4, 6 \ldots\ldots$ Also, this case is evidently one of mixed astatic action.

24.—Initial Eccentricities in a Simplified Case.—A structure is considered, which depends on the parameters, $u_1 \ldots\ldots u_n$, which are all astatic parameters with respect to the load, P. When all the critical loads, $Q_1 \ldots\ldots Q_n$, are different, then U and δ of the energy equation, $L = U - P\delta = \text{min.}$, can be expressed as in Formulas (66) and (63) in Article 17,

$$U = \frac{1}{2} \Sigma Q_n \delta_n u_n^2 ; \qquad \delta = \frac{1}{2} \Sigma \delta_n u_n^2$$

Now, assume a change of shape defined by $u_1 = e_1, \ldots\ldots u_n = e_n \ldots\ldots$, and assume that these deformations remain as a "permanent set" after the release of the load. It is also assumed that zero stresses correspond to zero load after the change has taken place, and that all other elastic properties, stiffness constants, etc., remain as before the change. In the changed structure, the original load, P, will no longer produce pure astatic action. The new case can be described as differing from the original case by eccentricities which are measured by $e_1 \ldots\ldots e_n \ldots\ldots$ By definition, $e_1 \ldots\ldots e_n \ldots\ldots$ will be called "the eccentricities", or, more explicitly, "the eccentricities of the parameters, $u_1 \ldots\ldots u_n \ldots\ldots$, with respect to the astatic load, P". The two structures, the original and the changed, will be called the "concentric" and the "eccentric" structures, respectively.

The quantities, $u_1 \ldots\ldots u_n \ldots\ldots$, can be used as parameters of both the eccentric and the concentric structure. The method of measuring the param-

eters starting from the initial shape of the concentric structure, will first be used; that is, in the eccentric structure, $u_1 = e_1, \ldots\ldots u_n = e_n \ldots\ldots$, represents the state of zero stresses, while $u_1 = \ldots = u_n = \ldots = 0$ indicates the shape which coincides with the initial shape of the concentric structure. This is one of the exceptional cases, in which the general rule laid down in Article 11, that zero values of all the parameters represent zero stresses, is not followed. As the stiffness constants are the same in both structures, the resilience quadric of the eccentric structure becomes:

$$U = \frac{1}{2} \Sigma\, Q_n\, \delta_n\, (u_n - e_n)^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (112)$$

When δ is measured, starting from the initial shape of the original structure, the expression, Formula (63), for δ remains unchanged, that is, we have also in the eccentric structure:

$$\delta = \frac{1}{2} \Sigma\, \delta_n\, u_n^2$$

Substituting Formulas (63) and (112) in the equation, $L = U - P\delta = \min.$, one finds the energy equation of the eccentric structure:

$$L' = \frac{1}{2} \Sigma\, (Q_n - P)\, \delta_n\, u_n^2 - \Sigma\, Q_n \delta_n\, e_n\, u_n = \min. \ldots\ldots\ldots (113)$$

Differentiation with respect to u_n gives:

$$u_n = e_n + \frac{P}{Q_n - P}\, e_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (114)$$

By comparing Formula (114) with the general Formula (74) derived in Article 17, it is seen that the value of the parameter, u_n, in the eccentric action can be found as the value of the same parameter in a certain heterostatic action which occurs in the original concentric structure, namely, the heterostatic action in which the astatic load, P, is combined with an orthostatic load which, if acting alone, would produce the initial shape of the eccentric structure. The character of this orthostatic load, W, and of its displacement, w, is defined by Formula (115):

$$W\, w = \Sigma\, Q_n\, \delta_n\, e_n\, u_n \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (115)$$

Effects which are measured, starting from the initial shape of the original structure, such as deflections from this initial shape, can be found by substituting the values of $u_1 \ldots\ldots u_n \ldots\ldots$, found by Formula (114), in the formulas which determine these effects in the original structure. Other effects, such as stresses or deflections from the initial shape of the eccentric structure, effects which are zero when $u_1 = e_1, \ldots\ldots u_n = e_n \ldots\ldots$, are found by substituting $u_1 - e_1, \ldots\ldots u_n - e_n \ldots\ldots$ for $u_1 \ldots\ldots u_n \ldots\ldots$ in the formulas for these effects in the original structure.

This result suggests that, in certain cases, it might be advantageous to measure the parameters starting not from the initial shape of the original structure, but from the initial shape of the eccentric structure. Let the parameters measured in this manner be $\bar{u}_1 \ldots\ldots \bar{u}_n \ldots\ldots$ They are derived from the parameters, $u_1 \ldots\ldots u_n \ldots\ldots$, simply by subtracting the eccentricities,

$e_1 \ldots\ldots e_n \ldots\ldots$; that is, $\ldots\ldots \bar{u}_n = u_n - e_n$, etc. Hence, the resilience is expressed as follows:

$$U = \frac{1}{2} \Sigma\, Q_n\, \delta_n\, \bar{u}_n^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (116)$$

By measuring δ as before, from the initial shape of the original structure, it is found that,

$$\delta = \frac{1}{2} \Sigma\, \delta_n\, (\bar{u}_n + e_n)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (117)$$

Substitution of Formulas (116) and (117) puts the energy equation, $L = U - P\delta = \text{min.}$, in the form:

$$L' = \frac{1}{2} \Sigma \left(Q_n - P \right) \delta_n \bar{u}_n^2 - P \Sigma\, \delta_n e_n \bar{u}_n = \text{min.} \ldots\ldots (118)$$

Differentiation with respect to $\bar{u}_n$ gives:

$$\bar{u}_n = \frac{P}{Q_n - P}\, e_n \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (119)$$

Since $u_n = \bar{u}_n + e_n$, Formula (119) is actually the same as Formula (114). Formula (118) leads to another interpretation of the eccentric action as a case of heterostatic action, and appears as the equation of a heterostatic action in which both the orthostatic and the astatic components of the load are measured in intensity by P. The orthostatic component is defined by its work, $Ww = P \Sigma\, \delta_n e_n \bar{u}_n$. The displacement in the direction of the astatic load in Formula (118) is expressed as $\delta' = \frac{1}{2} \Sigma\, \delta_n \bar{u}_n^2$, while Formula (117) expresses the displacement in the direction of the original load. The astatic component in Formula (118) may be obtained by adding certain loads proportional to P to the original load. Since the total given load, P, is the heterostatic load in Formula (118), however, the loads mentioned (which were to be added to the given load in order to produce the astatic load) will be equal and opposite to the loads which constitute the orthostatic component.

25.—Initial Eccentricities in the General Case.—Consider a structure of a more general type, using the notation given in Article 20. A load, P, is assumed to produce pure astatic action. A change or deformation is considered, in which the astatic parameters, $u_{na} \ldots\ldots u_{ni} \ldots\ldots$, belonging to the critical load, Q_n, take the values, $e_{na} \ldots\ldots e_{ni} \ldots\ldots$, and in which the other astatic parameters take values which are denoted correspondingly. These deformations are assumed to be retained as a permanent set after the release of the load, so that the changed shape is now that which corresponds to zero stresses and zero resilience. As in Article 24, the quantities, $e_{na} \ldots\ldots e_{ni} \ldots\ldots$, etc., are called, by definition, "the eccentricities of the parameters with respect to the load, P." The stiffness constants, such as the coefficients in the resilience quadric, are assumed again to remain the same as in the original structure. When the parameters and the deflections are measured from the original shape of the structure, that is, when the set of values, $u_{na} = e_{na} \ldots\ldots u_{ni} = e_{ni}$, etc., represents the initial shape of the changed eccentric structure, the expression

for the displacement, δ, in the direction of P will remain the same as in the original structure. According to Article 20, we have then Formula (87):

$$\delta = \Sigma\, \delta^{(n)} + \gamma\, v$$

where (Formula 89),

$$\delta^{(n)} = \frac{1}{2} \sum_{i} \delta_{ni}\, u_{ni}^{\,2} + \sum_{i,\,k} \delta_{ni,\,nk}\, u_{ni}\, u_{nk}$$

The expression for the resilience, U, is modified so as to make the set of values, $u_{na} = e_{na} \ldots\ldots u_{ni} = e_{ni} \ldots\ldots$, give $U = \min.$, that is, instead of Formula (86), we have for the eccentric structure:

$$U = \Sigma\, \bar{U}^{(n)} + \frac{1}{2}\, V v^{\,2} + T\,(t_1, t_2, \ldots\ldots) \ldots\ldots\ldots\ldots (120)$$

where,

$$\bar{U}^{(n)} = \frac{1}{2} \sum_{i} Q_n\, \delta_{ni}\, (u_{ni} - e_{ni})^2$$

$$+ \sum_{i,\,k} Q_n\, \delta_{ni,\,nk}\, (u_{ni} - e_{ni})\, (u_{nk} - e_{nk}) \ldots\ldots\ldots\ldots (121)$$

Substitution of Formulas (87), (89), (120), and (121) in the energy equation, $L = U - P\delta = \min.$, and differentiation with respect to u_{ni} gives

$$\frac{\partial L}{\partial u_n} = \left(Q_n - P\right) \left(\delta_{ni}\, u_{ni} + \sum_{k} \delta_{ni,\,nk}\, u_{nk}\right)$$

$$- Q_n \left(\delta_{ni}\, e_{ni} + \sum_{k} \delta_{ni,\,nkn}\, e_{nk}\right) = 0 \ldots\ldots\ldots\ldots\ldots (122)$$

where $k \neq i$. By exchanging the indices, $na, nb \ldots\ldots$, for ni, a set of linear equations is obtained from which the parameters, $u_{na}, u_{nb}, u_{ni} \ldots\ldots$, belonging to Q_n can be determined. The solution of the set of Formula (122), is:

$$u_{na} = e_{na} + \frac{P}{Q_n - P}\, e_{na} \ldots\ldots \qquad u_{ni} = e_{ni} + \frac{P}{Q_n - P}\, e_{ni} \ldots\ldots (123)$$

Formula (123) is virtually the same as Formula (114), derived for the simplified case. Formula (123) should be compared with Formula (97), the general formula for astatic parameters in heterostatic action. The comparison also shows that, in the case of the eccentric action in the structure of more general character, the values of the parameters can be determined as the values generated in a certain heterostatic action in the original structure; and as, in the simplified case, this heterostatic action is produced by the load, P, which is an astatic load in the original structure, combined with an orthostatic load which would produce the eccentricities, $e_{na} \ldots\ldots e_{ni}$, etc.

As in the simplified case, one may measure the parameters starting from the initial shape of the eccentric structure, that is, instead of u_{ni}, one may use, $\bar{u}_{ni} = u_{ni} - e_{ni}$. This method gives, analogous to Formula (119):

$$u_{ni} = \frac{P}{Q - P}\, e_{ni} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (124)$$

With the quantities, $\bar{u}_{ni}$, introduced as parameters in the expressions for resilience and displacement, a form of the energy equation will be derived which is analogous to Formula (118). One finds, then, as in the simplified

case, that the eccentric action can be interpreted as a heterostatic action in the eccentric structure. In that action, both the orthostatic component and the astatic component of the load, are proportional to P, the astatic component differing from the load, P, on the original structure by a load equal and opposite to the orthostatic component.

If a permanent set causes $v = v_e$ to be the value of the orthostatic parameter at zero stresses, then v_e added to the value of v produced in the original structure, gives the value of v in the changed structure, as measured from the initial shape of the original structure. This conclusion is easily verified by an application of the energy equation. In the same manner, if a permanent set causes one of the independent parameters, say, t_1, to take the value, t'_1, at zero stresses, then, as long as P is the only load, $t_1 = t'_1$ will remain as the constant value of that parameter. In other words, permanent sets represented by changes of the orthostatic parameter and of the independent parameter can be treated independently, that is, the effects due to such permanent sets can be combined with the effects due to the eccentricities of the parameters, $u_{n_0} \ldots\ldots u_{n_t} \ldots\ldots$, etc., by simple addition.

26.—Effects in Eccentric Action.—As a typical example, consider the hinged-end column, with a length, l, and a constant stiffness factor, EI. Deflections from the originally straight center line can be expressed as follows:

$$y = \Sigma u_n \sin \frac{n\pi x}{l},$$

where x is the distance from one end. The factors, u_n, will be used as the astatic parameters. The critical loads are expressed by the Euler formula,

$$Q_1 = Q = \frac{\pi^2 EI}{l^2}\ ; \quad Q_n = n^2 Q$$

The column, which had originally a straight center line, is now bent in such a way that permanent sets are left. The deflections, e, which remain when the load is released and the stresses are zero, may be expressed by a Fourier series of the form:

$$e = \Sigma e_n \sin \frac{n\pi x}{l}$$

According to the definitions made in Articles 24 and 25, $e_1 \ldots\ldots e_n \ldots\ldots$ are then the eccentricities of the astatic parameters, $u_1 \ldots\ldots u_n \ldots\ldots$, with respect to the end load, P. Denote, further: c = the distance from the center line to the extreme fibers, so that $\frac{I}{c}$ = the section modulus; A = the area of cross-section; and k = the radius of gyration, defined by $I = Ak^2$. The stresses, s, in the extreme fibers are among the effects which have particular interest, if y is measured from the original straight center line, which is also the line of the force, P; in that case, the stress is expressed as:

$$S = \frac{P}{A} + \frac{P.yc}{I}\ ; \quad \text{or,} \quad S = \frac{P}{A}\left(1 + \frac{y\,c}{k^2}\right)$$

According to Formula (123) or Formula (114), we have:

$$u_n = e_n + \frac{P}{Q_n - P} e_n = e_n + \frac{P}{n^2 Q - P} e_n$$

By substituting these values in the expression for y, and then introducing the value of y in the expression for S, we find:

$$S = \frac{P}{A}\left(1 + \frac{c}{k^2}\left(e + \Sigma \frac{P}{n^2 Q - P} e_n \sin \frac{n\pi x}{l}\right)\right) \ldots\ldots\ldots\ldots (125)$$

where $n = 1, 2, 3 \ldots\ldots$

Formula (125) gives the stress in the extreme fibers at any one point of the column. The reversed problem, that of finding the limiting value of P corresponding to a maximum allowable stress, S, may be treated by solving Formula (125), with respect to P. P is then found as a function of x and l. For each given value of l, the distance, x, has to be chosen so as to make P a minimum. In this manner, the limiting values of P will be found as a function of l. This function, say, $P = P(l)$, can be considered as the solution of Formula (125). In actual columns, it is impossible to secure an absolutely straight center line, an absolutely concentric loading, or a perfect evenness of the elastic qualities. The result is that eccentricities, such as those measured by e, or by $e_1, \ldots\ldots e_n$, cannot be avoided altogether in actual columns. With definite, properly chosen values of $e_1 \ldots\ldots e_n \ldots\ldots$, Formula (125), therefore, can be considered as a general column formula applying to actual columns, as long as their action depends essentially on the conditions before the elastic limit has been exceeded.* The column formulas commonly used in engineering design, such as that of Rankine, or the combination of the Euler formula with Johnson's parabolic formula, therefore, should appear as approximations to solutions of Formula (125). In the analysis of columns, one sometimes assumes a constant eccentricity which should then be considered as an "equivalent constant eccentricity", producing the same effect as the actual varying eccentricity. With e = constant, Formula (125) would lead to a solution, but the case is solved more easily by direct application of the differential equation of flexure. The result is the well known secant formula, which is given in many textbooks on Strength of Materials. With other end conditions, fixed ends, one free end, etc., formulas quite similar to Formula (125) can be derived. It may be said then that Formula (125) is a column formula of a general type, which applies to actual columns having small definite eccentricities.

If in the case solved by Formula (125), the greatest stress can be expected to be at or near the middle of the column, the solution can be simplified by introducing the definite value, $x = \frac{l}{2}$. This value gives $\sin \frac{n\pi x}{l}$ equal to: zero when n is even; $+1$ when $n = 1, 5, 9, \ldots\ldots$; and -1 when $n = 3, 7, \ldots\ldots$ Thereby, Formula (125) is reduced to:

$$S = \frac{P}{A}\left(1 + \frac{c}{k^2}\left(e_{center} + \frac{P}{Q - P} e_1 - \frac{P}{9Q - P} e_3 + \frac{P}{25Q - P} e_5 \ldots\right)\right) \ldots\ldots (126)$$

where $e_{center} = e_1 - e_3 + e_5 \ldots\ldots$

* Compare Kármán's work in which the influence of stresses above the elastic limit is investigated, *Mitteilungen über Forschungsarbeiten auf dem Gebiete des Ingenieurwesens*, v. 81 (1910).

The general case of eccentric action in any structure may now be considered. It is assumed that the load, P, would produce pure astatic action if it was not for the eccentricities, e_{na}, e_{nb}.....e_{nt}....., etc., of the astatic parameters, u_{na}, u_{nb}.....u_{nt}....., etc. One may consider some "effect", F. F will be assumed to be an effect which is expressed by the same function of the parameters whether the original or the eccentric structure is considered, the parameters being measured in both cases, from the initial shape of the concentric structure. In the special case previously treated, the stress, S, when expressed as indicated in terms of the deflections, y, is an effect of this kind, and so is, in general, any effect which is proportional to the deflections from the original shape. The general effect, F, was expressed by Formula (99), which, after substitution of Formula (100), may be written in the form:

$$F = \sum_n \sum_t F_{nt} u_{nt} + F_0 v + \bar{F}\ (t_1,\ t_2,\ .....) \qquad (127)$$

When P acts alone on the original concentric structure, and is different from any of the critical values — so that no buckling takes place — the effect is proportional to the orthostatic parameter, and may be written, in accordance with Formulas (127) and (83), as follows:

$$F_c = F_0 v = P \frac{F_0 \gamma}{V} \qquad (128)$$

Let t_1', t_2'....., be the eccentricities caused in the independent parameters, t_1, t_2....., by the permanent set. By substituting these values, Formula (128), and the values of the parameters, u_{nt}, given by Formula (123), in Formula (127), the effect in the eccentric action, is found to be as follows:

$$F = F_c + \sum_n \sum_t F_{nt} e_{nt} + \sum_n \frac{P}{Q_n - P} \sum_t F_{nt} e_{nt} + \bar{F}\ (t_1',\ t_2',\ ....). \qquad (129)$$

Formula (129), as might be expected, is quite similar to Formula (101), which determines the effects, F', in heterostatic action. As a matter of fact, Formula (129) might have been derived as a special case of Formula (101).

If F is an effect which varies from point to point, then F and the coefficients, F_{nt}, are functions of the location. Assume that the limiting strength of the structure is defined by some limiting value of F, which must not be exceeded. The lowest value of P found by solving Formula (129), with this value of F substituted, determines the upper limit beyond which the load, P, cannot be increased. In other words, Formula (129), like Formula (125) in the special case, can be used as a general formula to define the carrying capacity in eccentric action. It is practically impossible to build any structure absolutely exactly as designed. It follows that small eccentricities such as the e's in Formulas (125) and (129), must always be expected to exist. Equations such as Formula (129), with certain assigned values of the eccentricities, therefore, may be used to determine the limiting values of loads which are apparently astatic loads, and would be so if the structure was built with absolute exactness. It follows from the similarity between Formulas (129) and (125) that in a great number of the cases covered by the general Formula (129), it will be possible to substitute approximate formulas similar to the

solutions of Formula (125); that is, formulas similar to that of Rankine, Johnson's parabolic formula, etc., will be approximate solutions of the general Formula (129) in various cases of buckling.

27.—Determination of Astatic Actions and Astatic Parameters by the Expressions for Resilience and Displacement.—Assume that a certain structure is defined with sufficient exactness by a finite number of parameters, $x_1, x_2 \ldots\ldots$, which are not assumed, in general, to be astatic parameters. Let the resilience be expressed by the quadric:

$$U = \frac{1}{2} A_1 x_1^2 + \frac{1}{2} A_2 x_2^2 + \ldots. + A_{1,2} x_1 x_2 + \ldots\ldots\ldots\ldots (130)$$

Assume that the displacement in the direction of the load, P, is also expressed by a quadric, namely,

$$\delta = \frac{1}{2} a_1 x_1^2 + \frac{1}{2} a_2 x_2^2 + \ldots. + a_{1,2} x_1 x_2 + \ldots\ldots\ldots\ldots (131)$$

Then, the energy equation, $L = U - P\delta = \text{min.}$, gives:

$$\left.\begin{aligned} \frac{\partial L}{\partial x_1} &= (A_1 - a_1 P) x_1 + (A_{1,2} - a_{1,2} P) x_2 \\ &\quad + (A_{1,3} - a_{1,3} P) x_3 + \ldots. = 0 \\ \frac{\partial L}{\partial x_2} &= (A_{1,2} - a_{1,2} P) x_1 + (A_2 - a_2 P) x_2 \\ &\quad + (A_{2,3} - a_{2,3} P) x_3 + \ldots. = 0 \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \end{aligned}\right\} \ldots\ldots\ldots (132)$$

The equations, Formula (132), are solved by $x_1 = x_2 = \ldots\ldots = 0$. Solutions different from zero are possible, however, when the determinant of the equations, Formula (132), vanishes,* that is, when:

$$\left.\begin{aligned} &A_1 - a_1 P \quad A_{1,2} - a_{1,2} P \quad A_{1,3} - a_{1,3} P \ldots \\ &A_{1,2} - a_{1,2} P \quad A_2 - a_2 P \quad A_{2,3} - A_{2,3} P \ldots \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \end{aligned}\right\} = 0 \ldots (133)$$

If there are m parameters, Formula (133) is an equation of mth degree in P, and has, in general, m solutions. Assume that these solutions are $P = Q_1$, $Q_2 \ldots\ldots Q_n \ldots\ldots$, and take, for instance, $P = Q_n$. Substituted in Formulas (132), $P = Q_n$ gives the set:

$$\left.\begin{aligned} &(A_1 - a_1 Q_n) x_1 + (A_{1,2} - a_{1,2} Q_n) x_2 + (A_{1,3} - a_{1,3} Q_n) x_3 + \ldots. = 0 \\ &(A_{1,2} - a_{1,2} Q_n) x_1 + (A_2 - a_2 Q_n) x_2 + (A_{2,3} - a_{2,3} Q_n) x_3 + \ldots. = 0 \\ &\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \end{aligned}\right\} \ldots (134)$$

With $x_1 = c_{n1} u_n$, where c_{n1} is a chosen constant, and $u_n =$ any value, $m - 1$, of the equations, Formula (134), gives solutions which satisfy the remaining equation, hence, the solutions of the equations, Formula (134), may be expressed, as follows:

$$x_1 = c_{n1} u_n ; \qquad x_2 = c_{n2} u_n ; \qquad x_3 = c_{n3} u_n ; \ldots\ldots\ldots (135)$$

where u_n can take any value. u_n can be used as a parameter defining the variation expressed in Formula (135). Furthermore, u_n can be interpreted as

* The vanishing of a determinant is used by several writers as a criterion of buckling or of an equilibrium ceasing to be stable; for example, R. V. Southwell, *Philosophical Transactions*, Royal Soc., A, v. 213 (1914), p. 218; A. Ostenfeld, "Teknisk Statik", II, ed. 1913, p. 490; H. Zimmerman, *Sitzungsberichte* der. k. preuss. Akad. der Wissenschaften (1909), p. 193.

an astatic parameter. Its corresponding critical load is $P = Q_n$. By making $P = Q_1, Q_2 \ldots\ldots$, successively, and repeating the same operations, the set of astatic parameters, $u_1, u_2 \ldots\ldots$, may be determined completely.

One conclusion reached is that pure astatic action occurs when both the displacement in the direction of the load and the resilience are quadrics in the parameters. It is easy to verify the fact that this conclusion will continue to hold when additional terms, $\frac{1}{2} V v^2 + T(t_1, t_2 \ldots)$, in U, and γv in δ, are introduced. v and $t_1, t_2 \ldots$ will be recognized at once as orthostatic and independent parameters, respectively.

If δ had been a linear function of the parameters instead of a quadric, P would have been an orthostatic load. In a case of more general nature, the displacement in the direction of the load, P, is a quadratic function containing some linear terms. The total displacement may then be expressed as $\delta' = \delta + w$, where δ is a quadric of the form, Formula (131), while w contains the linear terms. In this case, the total load, P, may be interpreted as consisting of two components, each measured in intensity by the quantity, P. One component of P is an astatic load in the direction of the displacement, δ, the other component of P is an orthostatic load in the direction of the displacement, w. One concludes that if the resilience is a quadric in terms of a certain set of parameters, and if the displacement in the direction of a given load is expressed in terms of these parameters as a quadratic function containing linear terms, the action produced is a heterostatic action. This heterostatic action is recognized as one of the general type produced under the combined influence of an orthostatic and an astatic component of the load.

V.—Differential Equations Applying to Some Definite Cases.

28.—The Methods of Solution: Differential Equations and the Energy Method.—The problems treated herein are usually solved by one of two fundamental methods, one of which is based on the energy principle and the other on the direct statical principles of equilibrium. Both methods are represented at many places in the works mentioned in the Bibliography (Part VII). The general theory in Part IV of this investigation was based on the energy principle. The problem of equilibrium is reduced by the energy principle to a problem of energy minimum, or, to a variation problem. The analyses in Part IV show clearly that this method of attack is particularly effective in the derivation of general principles; but the history of technical statics has shown that the principle of least action can be applied with advantage also to structural problems of definite and specific character. The fundamental work of Castigliano* on statically indeterminate structures is an example. Castigliano's method of least work was applied primarily to problems the solution of which depends on a finite number of unknown or "indeterminate" quantities. In 1909, W. Ritz† indicated a method by which Castigliano's principles can be

* A. Castigliano, "Théorie de l'équilibre des systèmes élastiques et ses applications", Torino, 1879.

† W. Ritz, "Ueber eine neue Methode zur Lösung gewisser Variationsprobleme der mathematischen Physik", Crelles' *Journal für reine und angewandte Mathematik*, v. 135 (1909).

used even when the structure depends on an infinite number of "indeterminate" parameters. Results are then expressed in series giving successive approximations. Ritz's method has been applied since by several writers in the analysis of continuous structures, such as slabs, domes, water tanks, etc. S. Timoshenko* used the method extensively in the analysis of astatic action. The case of a column with varying section, for example, is analyzed conveniently by Ritz's method.† The conclusion is that the energy principle can be used with advantage in the analysis of the general questions and of some of the more complex specific questions.

Other cases are analyzed, however, as easily or more easily by the use of the direct statical principles of equilibrium. These principles are expressed in most cases of astatic or heterostatic action by certain differential equations which represent the conditions of equilibrium of each element of the structure. Thus, the solution of the problem is made to depend on the solution of certain differential equations. This method is advantageous in the analysis of the simple structures, such as single columns, curved members, and slabs. In the following Articles, the derivation of the differential equations of heterostatic action in such structures will be indicated. By omitting either the astatic or the orthostatic component of the load, one may analyze the orthostatic or the astatic actions, respectively, and, in particular, one may determine the nature of the astatic parameters. Afterward, the heterostatic action may be investigated by the formulas for combination which were indicated in Part IV, particularly by Formulas (74), (75), (97), (101), and (102). The investigation, except in special cases, will not proceed further than the determination of these differential equations. As to their solution in detail, and their application to individual cases, reference is made to the several specific treatments which are listed in the Bibliography (Part VII).

29.—Straight Columns.‡—Cases in which the axial load is applied continuously throughout the length of the column, or in which there is a continuous transverse elastic support, have been analyzed by Timoshenko, Greenhill, and Zimmerman.§ Such columns will not be included in the present analysis. The discussion will be confined to cases in which the axial load is transferred at a finite number of definite points and in which the transverse support is at definite points. In such cases, the column may be divided into sectors, each of which is between two consecutive points at which there is a transverse reaction or a change of the axial load. Fig. 9 shows such a sector. The distances, x, along the column are measured from the lower end of this sector. The x-axis may be fixed in space or attached in some way to points of the center line of the column. The deflections, y, are measured from the x-axis, positive toward the right. The axial load, P, is the astatic component of the load. P may be inclined relative to the x-axis, as shown in Fig. 9 (a), but, in this case, it may always be replaced, as indicated in Fig. 9 (b), by a load, P, along the x-axis combined with a horizontal force, X, and a couple, Y, at the lower end.

* See Bibliography, Part VII, Section *A*.

‡ Bibliography, Part VII, Section *C*.

§ Bibliography, Part VII, Sections *A* and *C*.

X and Y may be considered as constants which are to be determined by the end conditions. Their positive directions are shown in Fig. 9 (b). The remainder of the notation follows:

Let M = bending moment due to the orthostatic or transverse load alone. M is considered as positive when causing compression to the left, tension to the right.

M' = bending moment under the combined influence of the transverse and the axial load, considered positive in the same direction as M.

EI = stiffness factor (modulus of elasticity times moment of inertia of the cross-section). EI may vary as a function of x.

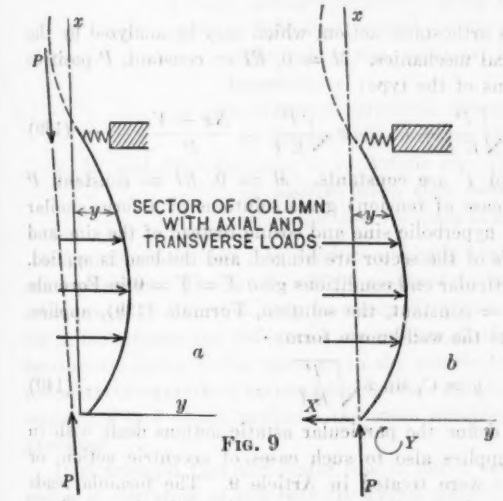

FIG. 9

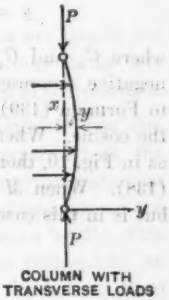

FIG. 10

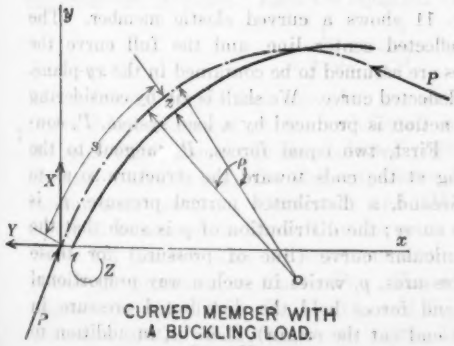

FIG. 11

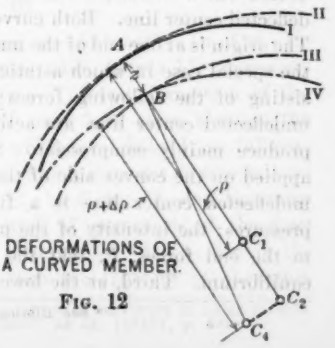

FIG. 12

With positive directions as indicated, the equation of flexure is,

$$E\,I\,\frac{d^2\,y}{d\,x^2} = -\,M' \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (136)$$

From Fig. 9 (*b*), it follows that:

$$M' = M + Py + Xx + Y \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (137)$$

therefore, the differential equation applying to the sector is:

$$E\,I\,\frac{d^2\,y}{d\,x^2} + Py + Xx + Y = -\,M \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (138)$$

where the constants, X and Y, are to be chosen so as to satisfy the end conditions. The end conditions are defined by the character of the supports, by the methods of transfer of the axial load, or by the connection with adjoining sectors above and below.

$P = X = Y = 0$ gives orthostatic action, which may be analyzed by the common methods of technical mechanics. $M = 0$, $EI =$ constant, P positive (compression) gives solutions of the type:

$$y = C_1 \sin x\sqrt{\frac{P}{E\,I}} + C_2 \cos x\sqrt{\frac{P}{E\,I}} - \frac{Xx + Y}{P} \ldots\ldots\ldots\ldots\ldots\ldots (139)$$

where C_1 and C_2 as X and Y are constants. $M = 0$, $EI =$ constant, P negative (representing the case of tension) gives solutions of a form similar to Formula (139), but with hyperbolic sine and cosine instead of the sine and the cosine. When both ends of the sector are hinged, and the load is applied, as in Fig. 10, then these particular end conditions give $X = Y = 0$ in Formula (138). When $M = 0$, $EI =$ constant, the solution, Formula (139), applies, but is in this case reduced to the well-known form:

$$y = C_1 \sin x\sqrt{\frac{P}{E\,I}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (140)$$

Formulas (139) and (140) define the particular astatic actions dealt with in Part II. Formula (139) applies also to such cases of eccentric action, or action with end couples, as were treated in Article 9. The formula leads directly to Formula (15) for the bending moment produced in these actions.

*30.—Curved Members.**—Fig. 11 shows a curved elastic member. The dotted curve indicates the undeflected center line, and the full curve the deflected center line. Both curves are assumed to be contained in the xy-plane. The origin is at one end of the undeflected curve. We shall begin by considering the special case in which astatic action is produced by a load system, P, consisting of the following forces: First, two equal forces, P, tangent to the undeflected center line, are acting at the ends toward the structure so as to produce mainly compression. Second, a distributed normal pressure, p, is applied on the convex side of the curve; the distribution of p is such that the undeflected center line is a funicular curve (line of pressure) for those pressures; the intensity of the pressures, p, varies in such a way proportional to the end forces, P, that the end forces hold the distributed pressure in equilibrium. Third, at the lower end (at the origin), there is, in addition to

* See Bibliography, Part VII, Section *G*.

the concentrated force, P, an end load which may be resolved into the three components X, Y, and Z. The two forces, X and Y, act through the origin in the directions $+y$ and $-x$, respectively (as indicated by the arrows in the diagram); and the couple, Z, acts in a clockwise direction. X, Y, and Z may be considered as reactions produced by the remainder of the total astatic load, P, and are zero when $P = 0$. Fourth, at the upper end there is, in addition to the concentrated force, P, a load similar to that of the load, X, Y, Z, at the lower end. All these loads are parts of the astatic component, P, of the total load. In the general case of heterostatic action, there is, in addition, an orthostatic load-component, W.

It is further denoted that:

s = the distance measured along the curve from the origin.

z = the deflection normal to the curve, positive toward the right when the observer looks in the direction of increasing s.

ρ = the radius of curvature, measured positive from the curve in the positive direction of z.

M, M', and EI = the same as in Article 29. The moments are considered as positive when they cause compressions to the left when the observer looks in the direction of increasing s.

The orthostatic load may produce not only bending moments, M, but also axial pressures. The latter will be assumed to be small compared with the astatic load, P. Then, it may be assumed, with a sufficient approximation as far as the stresses and deflections are concerned, that the axial pressure in the heterostatic action is the same as in the astatic action produced by P. This procedure is equivalent to considering the orthostatic load as replaced by an equivalent load which produces the same bending moment, M, but no axial pressures.

It is assumed that the center line is not a very sharp curve, so that the radius of curvature at any point is several times the transverse dimensions of the structural member. Then the equation of flexure may be written:

$$\frac{1}{\rho + \Delta\rho} - \frac{1}{\rho} = -\frac{M'}{EI} \qquad (141)$$

The left-hand expression may be transcribed as follows:* In Fig. 12, Curve I is an element of the undeflected curve, while Curve IV represents the same curve element in the deflected position. The transformation of the element, Curve I, into the element, Curve IV, may take place through the intermediate positions, Curves II and III, which are defined as follows: Curve II is tangent to Curve I at the point A, which is under consideration; Curve III has the same center of curvature, C_2, as Curve II, and the same radius of curvature as Curve IV. The centers of curvature of the four elements in Fig. 12 are C_1, C_2, C_2, and C_4, respectively. Let z_2 denote the deflection of Curve II relative to Curve I, then the increase of curvature

* Another derivation based on the formula for the radius of curvature in polar co-ordinates is given in A. Ostenfeld's "Teknisk Elasticitetslære", 3d ed. (1916), p. 480.

(curvature = reciprocal of radius of curvature) at the transformation, Curve I to Curve II, is expressed as $\frac{d^2 z_2}{ds^2}$. At the transformation, Curve II to Curve III, the increase of curvature is $\frac{1}{BC_2} - \frac{1}{AC_2}$, but when C_1 C_2, and the deflection $AB = z$, are small distances, this difference is very nearly equal to, and may be replaced by, the quantity, $\frac{1}{BC_1} - \frac{1}{AC_1} = \frac{z}{\rho^2}$. The transformation, Curve III to Curve IV, does not change the curvature any further. Since $\frac{d^2 z}{ds^2} = \frac{d^2 z_2}{ds^2}$, it follows that the total increase of curvature, or the left side in Formula (141), is $\frac{d^2 z}{ds^2} + \frac{z}{\rho^2}$. Hence, the equation of flexure can be written as follows:

$$EI\left(\frac{d^2 z}{ds^2} + \frac{z}{\rho^2}\right) = -M' \quad \text{.....(142)}$$

Consideration of Fig. 11 gives in the heterostatic action,

$$M' = M + Pz + Xx + Yy + Z,$$

and this expression, substituted in Formula (142), gives the equation of flexure:

$$EI\left(\frac{d^2 z}{ds^2} + \frac{z}{\rho^2}\right) + Pz + Xx + Yy + Z = -M' \quad \text{.....(143)}$$

The corresponding Formula (138), applying to straight columns, represents the special case of Formula (143), in which $\rho = \infty$.

With ρ = constant, EI = constant, $M = 0$, and with certain end conditions, the solution of Formula (143) is a trigonometric function, sine or cosine of angles proportional to s. Such solutions define the astatic actions of circular cylinders carrying a uniform outside pressure.

In deriving the differential equation, Formula (143), it was assumed that the pressure, p, was at all places perpendicular to the curve, s. Under such circumstances, the axial pressure in the astatic action is the same in all cross-sections, and equal to the end pressure, P. However, an astatic action is also possible, in which the axial pressure, N, varies. The variation from the value, P, which is the value of N at the point, $s = 0$, is caused by tangential components of the distributed pressure, p. The general condition of pure astatic action is that the undeflected center line is a pressure line for the force set, P, p. The axial forces, N, appear as rays in the corresponding force polygon (or force curve). It follows that N at each point varies proportionally to P, so that P may still be used as a measure of the intensity of the astatic load. When the force set, P, p, can be assumed to remain in a constant position after the flexure, the differential equation will be the same as Formula (143), except that N is substituted for P. As in the special case, the constants, X, Y, and Z, as well as the integration constants must be determined from the end conditions.

*31.—Slabs.**—Fig. 13 shows a part of the slab in its undeflected position. The xy-plane is the central plane of the undeflected slab. The y-axis is assumed to be vertical and the x-axis to be horizontal. The astatic load consists of the following uniformly distributed forces, all parallel to the xy-plane and acting in the xy-plane as long as the slab is undeflected:

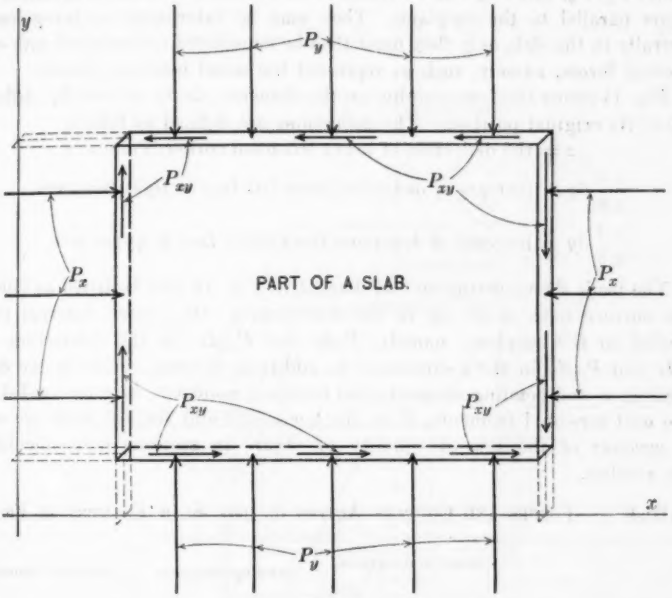

FIG. 13.

Let P_x = the horizontal end pressure in the xy-plane per unit vertical distance.

P_y = the vertical end pressure in the xy-plane per unit horizontal distance.

P_{xy} = the distributed force per unit length along the edges: Horizontal force along the horizontal edges, vertical force along the vertical edges. These horizontal and vertical forces are equal per unit length on account of the law of "shearing forces in pairs".

The orthostatic load is:

w = the surface pressure perpendicular to the slab per unit area. In the general case, w is a function of x and y.

* See Bibliography, Part VII, Section *J*. The derivation of the equation of flexure of slabs in rectangular co-ordinates with loads normal to the surface is given in several treatises, see, for example, A. Föppl, "Technische Mechanik", v. 5, 1907 ed., pp. 97 *et seq.* Concerning the terms in the flexure equation, which are due to the end pressures, see, for example, A. E. H. Love, "Theory of Elasticity" (1906), pp. 528-529. A flexure equation of general form, which includes the effects of end pressures and end shears, is given in B. de Saint-Venant's annotated translation of Clebsch's "Theory of Elasticity", Paris, 1883, Note by Saint-Venant, p. 704, Equation (e_1).

The pressures, P_x and P_y, give uniform horizontal and vertical compressions in the undeflected slab, while P_{xy} produces a uniform horizontal and vertical shear. It is assumed that this uniform distribution will still exist after the slab has deflected, and this assumption is generally warranted as long as the deflections are small compared with the thickness of the slab. The conclusion is that P_x, P_y, and P_{xy} will be transmitted as constant internal pressures and shears parallel to the xy-plane. They may be interpreted as being located centrally in the slab, only they must then be considered as combined with other internal forces, namely, such as represent the usual bending stresses.

Fig. 14 shows the forces acting on the elements, $dx\,dy$, after it has deflected out of its original position. The deflections are defined as follows:

z = the deflection of lower left-hand corner, Point x, y;

$\frac{\partial z}{\partial x}\,dx$ = increase of deflection from left face to right face; and

$\frac{\partial z}{\partial y}\,dy$ = increase of deflection from lower face to upper face.

The loads shown acting on the element in Fig. 14 may be listed as follows: The surface load, $w\,dx\,dy$, in the direction, z; the central internal forces parallel to the xy-plane, namely, $P_x dy$ and $P_{xy} dx$, in the x-direction, and $P_y dx$ and $P_{xy} dy$ in the y-direction; in addition, internal shears in the directions, $\pm z$, and bending moments and torsional moments, as given in Table 4. The unit torsional moments, Z, in the horizontal and vertical faces are equal on account of the law of equality of shears in sections perpendicular to one another.

TABLE 4.—Forces and Couples Acting on the Slab Element in Fig. 14.

	Shear in directions, $\pm z$.	Bending moments.	Torsional moments.
Left face	$V_x\,dy$	$X\,dy$	$Z\,dy$
(Direction)	$(-z)$	(xz)	(yz)
Right face	$\left(V_x + \frac{\partial V_x}{\partial x}\,dx\right) dy$	$\left(X + \frac{\partial X}{\partial x}\,dx\right) dy$	$\left(Z + \frac{\partial Z}{\partial x}\,dx\right) dy$
(Direction)	$(+z)$	(zx)	(zy)
Lower face	$V_y\,dx$	$Y\,dx$	$Z\,dx$
(Direction)	$(-z)$	(yz)	(xz)
Upper face	$\left(V_y + \frac{\partial V_y}{\partial y}\right) dx$	$\left(Y + \frac{\partial Y}{\partial y}\,dy\right) dx$	$\left(Z + \frac{\partial Z}{\partial y}\,dy\right) dx$
(Direction)	$(+z)$	(zy)	(zx)

By equating the sum of the forces in the z-direction to zero, and dividing by $dx\,dy$, the following condition is found:

$$\frac{\partial V_x}{\partial x} + \frac{\partial V_y}{\partial y} + w = 0 \qquad (144)$$

By equating the sum of the moments about a vertical line through the center of the element to zero, and dividing by $dx\,dy$, we find:

$$\frac{\partial X}{\partial x} + \frac{\partial Z}{\partial y} = V_x + P_x \frac{\partial z}{\partial x} + P_{xy} \frac{\partial z}{\partial y} \quad \ldots\ldots\ldots\ldots (145)$$

In the same way, by using a moment axis through the center, parallel to the x-axis, we find:

$$\frac{\partial Y}{\partial y} + \frac{\partial Z}{\partial x} = V_y + P_y \frac{\partial z}{\partial y} + P_{xy} \frac{\partial z}{\partial x} \quad \ldots\ldots\ldots\ldots (146)$$

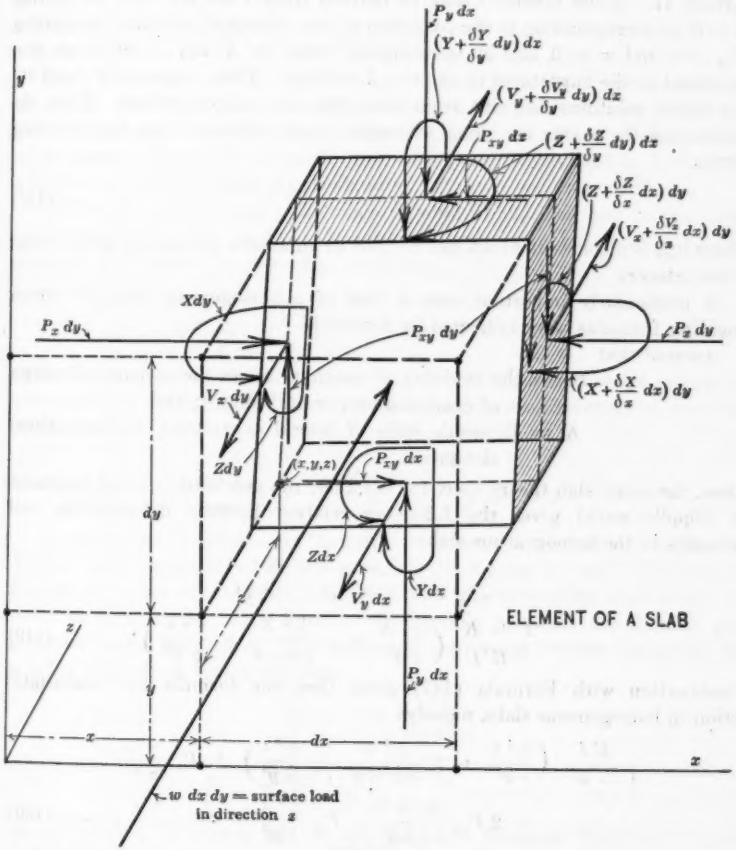

FIG. 14.

By differentiation of Formula (145) with respect to x, and Formula (146) with respect to y, and by adding and combining with Formula (144), we find:

$$\frac{\partial^2 X}{\partial x^2} + 2\,\frac{\partial^2 Z}{\partial x\,\partial y} + \frac{\partial^2 Y}{\partial y^2}$$
$$= -w + P_x \frac{\partial^2 z}{\partial x^2} + 2\,P_{xy} \frac{\partial^2 z}{\partial x\,\partial y} + P_y \frac{\partial^2 z}{\partial y^2} \quad \ldots\ldots\ldots (147)$$

Formula (147) is a general equation of equilibrium on which theory dealing with specific cases may be based. It applies to continuous slabs whether or not they are homogeneous, and whether they are isotropic, that is, having the same properties in different directions, or æolotropic, having different properties in different directions. An example of the latter is the two-way, reinforced concrete slab, in which one may have to assume different stiffnesses in the various directions. Formula (147) applies also to the case of the double system of closely spaced beams for which buckling formulas were given in Article 11. These formulas may be derived from Formula (147) by putting $Z = 0$, as corresponding to the condition of zero torsional resistance, by putting $P_{xy} = 0$ and $w = 0$, and by substituting terms for X and Y, which are proportional to the curvatures in the two directions. Then, values of P_x and P_y, for which solutions different from zero exist, are critical values. When the x-axis and the y-axis are along two edges, such solutions have the following form:

$$z = u_{mn} \sin \frac{m \pi x}{a} \sin \frac{m \pi y}{b} \quad \ldots\ldots\ldots\ldots\ldots\ldots (148)$$

where u_{mn} is a constant which can be used as an astatic parameter, while m and n are integers.

A particularly important case is that of a homogeneous slab, for which buckling formulas were indicated in Article 10.

Assume that

EI = the modulus of elasticity times the moment of inertia of cross-section per unit length; and

K = Poisson's ratio of lateral contraction to longitudinal elongation.

Then, the usual slab theory (see, for instance, the previously quoted treatment in Föppl's work) gives the following relation between deformations and moments in the homogeneous slab:

$$\frac{\partial^4 z}{\partial x^4} + 2 \frac{\partial^4 z}{\partial x^2 \partial y^2} + \frac{\partial^4 z}{\partial y^4} = - \frac{1 - K^2}{E I} \left(\frac{\partial^2 X}{\partial x^2} + 2 \frac{\partial^2 Z}{\partial x \partial y} + \frac{\partial^2 Y}{\partial y^2} \right) \quad \ldots\ldots\ldots (149)$$

Combination with Formula (147) gives then the formula for heterostatic action in homogeneous slabs, namely:

$$\frac{E I}{1 - K^2} \left(\frac{\partial^4 z}{\partial x^4} + 2 \frac{\partial^4 z}{\partial x^2 \partial y^2} + \frac{\partial^4 z}{\partial y^4} \right) + P_x \frac{\partial^2 z}{\partial x^2} + 2 P_{xy} \frac{\partial^2 z}{\partial x \partial y} + P_y \frac{\partial^2 z}{\partial y^2} = w \quad \ldots\ldots\ldots\ldots (150)$$

As an example, consider the rectangular slab treated in Article 10, which is simply supported along straight edges and has the spans, a and b. It is assumed that no shearing forces like P_{xy} are acting. With $w = 0$, $P_{xy} = 0$, and with co-ordinate axes along two edges, Formula (150) will be satisfied by solutions of the form, Formula (148), on the condition that P_x and P_y take such special, mutually dependent values, Q_a and Q_b, as are indicated by

Formula (21) in Article 10. These are the critical values which produce astatic actions.

The writer will indicate how the bending moment at the center of a simply supported rectangular slab may be found by integration of Formula (150). He will first consider the orthostatic action produced by a uniform surface load, w, acting alone. The computations are simplified by assuming that:

$b = \pi$ = short span;

$a = \dfrac{\pi}{\alpha}$ = long span;

$w = \dfrac{1}{\pi^2}$ = surface load per unit area.

These values give $wb^2 = 1$. The use of a as the ratio of the spans is in accordance with the notation in Article 10, and the results found with these special values may be made to apply in the more general case by multiplication by the proper factors. For example, wb^2, with the notation used in Article 10, is the factor used in expressing the bending moments per unit width.

The x-axis and the y-axis are taken parallel to the long and to the short span, respectively. The origin is at the center, and the surface load, w, may be expressed in a double Fourier series, as follows:

$$w = \frac{16}{\pi^4} \sum_{1,3..}^{m} \sum_{1,3..}^{n} \frac{-(-1)^{\frac{m+n}{2}}}{m\,n} \cos m\,\alpha\,x \,.\, \sin n\,y \quad = \frac{1}{\pi^2} \quad \ldots(151)$$

This expression is substituted in Formula (150). In the orthostatic action, we have $P_x = P_y = P_{xy} = 0$. Then, we find the following solution of Formula (150):

$$z = \frac{16}{\pi^4} \frac{(1-K^2)}{E\,I} \sum_{1,3..}^{m} \sum_{1,3..}^{n} \frac{-(-1)^{\frac{m+n}{2}}}{m\,n\,(\alpha^2 m^2 + n^2)^2} \cos m\,\alpha\,x \,.\, \cos n\,y \quad \ldots(152)$$

In indicating formulas for bending moments in orthostatic action in Article 10, Poisson's ratio, K, was assumed to be equal to zero. Reasons for deriving formulas on this basis, even when K is known to differ from zero, were stated in Article 10. With $K = 0$, the bending moments are directly proportional to the curvatures. The following expression is then found for the bending moment in the short span:

$$Y = -E\,I \frac{\delta^2 z}{\delta\, y^2}$$

$$= \frac{16}{\pi^4} \sum_{1,3..}^{m} \sum_{1,3..}^{n} \frac{-(-1)^{\frac{m+n}{2}}\, n}{m\,(\alpha^2 m^2 + n^2)^2} \cos m\,\alpha\,x \,.\, \cos n\,y \quad \ldots\ldots(153)$$

By introducing the factor, wb^2, on the right side, Formula (153) can be made to apply to any spans and unit load. Then, by substituting $x = y = 0$, which corresponds to the center of the slab, the following expression is found for the bending moment in the short span at the center:

$$M_b = \frac{16\,w\,b^2}{\pi^4} \sum_{1,3..}^{m} \sum_{1,3..}^{n} \frac{-(-1)^{\frac{m+n}{2}}\, n}{m\,(\alpha^2 m^2 + n^2)^2} \quad \ldots\ldots\ldots \quad (154)$$

This double infinite series defines a function of wb^2 and a. It can be shown that the function, Formula (154), is rather well approximated by the simplified Formula (28), which was indicated in Article 10.

Each separate term in the double infinite series, Formulas (152), (153), and (154), is seen to represent a case of pure astatic equilibrium as produced by the end loads, P_x and P_y, alone (compare Formula (148)), that is, these series are of the type represented in Formula (99) which may be written in this case, as follows:

$$F = \Sigma F^{(n)} \quad \ldots\ldots (155)$$

where F and $F^{(n)}$ are effects in orthostatic and astatic actions, respectively. Formula (155) may also be interpreted as a form of equation, Formula (60), which is the corresponding formula applying in the simplified case which was treated in Article 17. Formula (155) is also of the same form as Formula (11) in Article 7, which expresses the moments in columns. In accordance with Formula (102), the corresponding effect in heterostatic action is expressed, as follows:

$$F' = F + \Sigma \frac{P}{Q_n - P} F^{(n)} \quad \ldots\ldots (156)$$

Formula (156) may be interpreted as a case of Formula (75). It is of a form similar to Formula (12). In applying Formulas (155) and (156) to the present case of flexure, the index, n, should be replaced by a double index such as m, n. The writer will confine himself to the cases in which $m = n = 1$ gives the smallest critical value, Q, of the astatic load, P. The result is that Formula (156), with the separate terms in Formula (154) substituted for $F^{(n)}$, is a series which begins to converge rapidly immediately after the term corresponding to $m = n = 1$. When the higher terms in the summation in Formula (156) are omitted, that is, when only the first term, which corresponds to $m = n = 1$, is included, the following approximate value is found for the term which must be added to the moment, M_b, in Formula (154) when the end loads, P, are introduced in addition to the already existing surface load, w:

$$M_b'' = \frac{16}{\pi^4} \frac{w\, b^2}{(\alpha^2 + 1)^2} \frac{P}{Q - P} \quad \ldots\ldots (157)$$

Formula (157) is the same as Formula (30) in Article 10.

The case of the double system of crossing-beams for which formulas were given in Article 11, is analyzed in a similar way. The orthostatic flexure due to the distributed load, w, alone depends on the differential equation:

$$\frac{\delta^4 z}{\delta x^4} + \frac{\delta^4 z}{\delta y^4} = \frac{w}{EI} \quad \ldots\ldots (158)$$

which can be integrated by the same method as that used in integrating Formula (150), in the case of the rectangular slab. By means of a trigonometric series similar to Formulas (151), (152), and (153), the following value is found for the moment at the center:

$$M = \frac{16\, w\, b^2}{\pi^4} \sum_{1,3\ldots}^{m} \sum_{1,3\ldots}^{n} \frac{-(-1)^{\frac{m+n}{2}} m}{n\,(m^4 + n^4)} = 0.077\, wb^2 \ldots (159)$$

The value, $0.077\ wb^2$, was indicated by Formula (36) in Article 11. The first term in Formula (159) is as follows:

$$\frac{8}{\pi^4}\ wb^2 = 1.07 \times 0.077\ wb^2 \ldots\ldots\ldots\ldots\ldots\ldots (160)$$

It is assumed again that the lowest critical astatic load, Q, corresponds to $m = n = 1$. By substituting Formula (160) for the first term, $F^{(n)}$, in the summation in Formula (156), and omitting the remainder of the terms which, in the case considered, may be assumed to be very small, the following approximate expression is found for the moment at the center in the heterostatic action which is caused by the combined influence of the end loads, P, and the surface load, w:

$$M' = 0.077\ wb^2 \left(1 + 1.07\ \frac{P}{Q - P}\right) \ldots\ldots\ldots\ldots (161)$$

Formula (161) is the same as Formula (37) in Article 11.

VI.—Summary.

32.—The investigation deals with structural actions in which the stresses are not proportional to the loads, although the proportional limit of the material has not been exceeded and the deflections remain small. A number of examples of such actions have been mentioned in the Introduction, in Article 1. A simple example is that of the buckling of a slender column under an axial load. A central axial load acting alone on a straight homogeneous column produces "astatic" action; a transverse load acting alone would produce "orthostatic" action; while a combination of the two loads produces a "heterostatic" action. The three terms—orthostatic, astatic, and heterostatic—as applying to structural actions in general, were introduced in Article 1, where orthostatic action is characterized by proportionality of the stresses to the loads; astatic action by the neutral elastic equilibria; and heterostatic action by the combined action of loads which separately would produce orthostatic or astatic action. In the Bibliography (Part VII), a great number of previous investigations of astatic actions are listed.

The present investigation deals with astatic action, and, in particular, with heterostatic action. The study of the latter was made possible by the introduction of a set of "astatic parameters" (Article 15), which were found to have peculiar properties, in particular that of "orthogonality". The general theory is given in Part IV. The use of the astatic parameters leads to simple and general solutions of otherwise complex and difficult problems. The main results of the theory are expressed in Formulas (59), (109), (74), and (97), for the parameters, and Formulas (75), (101), and (102), for the effects in general in heterostatic action.

Although the general theory makes use of the principle of least action, which is expressed in energy equations, certain specific cases of the simpler kind are solved more easily by the direct statical principles which are expressed in differential equations of equilibrium. In Part V, differential equations are set up, which represent cases of straight columns (Formula (138)), curved members (Formula (143)), and slabs (Formulas (147) and

(150)). Special solutions of these equations lead to the specific cases for which formulas are given in Parts II and III.

Part II deals with columns carrying axial and transverse loads at the same time. The solutions depend on the general Formula (12), which is a special case of the Formulas (75), (101), and (102) which are derived in Part IV. The results are found in terms of infinite series, such as Formula (7), but these series appear to be rapidly convergent in the cases investigated, and they can be replaced by approximate formulas with only a few terms in each. Such approximate formulas are given in Table 1, Article 4, and are so simple that they may be used readily by designers of structures. Numerical and graphical results are given in Article 6. In Part III, formulas are given for buckling of slabs and systems of crossing-beams. These cases, also, are special cases to which the results of the general analysis in Part IV may be applied directly.

VII.—Classified Bibliography.

The Bibliography which follows, does not attempt to include references dealing exclusively with straight columns which have constant cross-sections and which carry axial end loads only. This case is treated more or less extensively in almost every textbook on Mechanics of Materials. It is sufficient for the present purpose to point to Euler's analysis of columns, which dates back to 1757, and to the progress which has been marked by the introduction of such formulas as those of Rankine, the parabolic, and the straight-line formulas. A great deal of experimental work has been completed in this field. The deviations from Euler's formula are usually explained by the inevitable presence of small initial eccentricities. In fact, some of the texts* interpret the formulas mentioned as approximate representations of the secant formula which applies to eccentric loading, and which may be used when some definite "equivalent initial eccentricity" has been introduced.

One work on straight columns, of a comparatively recent date, is mentioned in the Bibliography. It is the investigation of columns by Kármán (Section *B*). Kármán's experiments and analysis are noteworthy, due to the light which they throw on the influence of stresses above the proportional limit. This matter is important with reference to the shorter columns. Among the other works mentioned in the Bibliography, particular attention is called to S. Timoshenko's treatment of a great variety of cases of elastic buckling (Section *A*), and also to the analysis of cylindrical shells by Goupil (Section *G*), in which a special case of the general formula for heterostatic action is derived. It is in the nature of the matter that the following Bibliography cannot lay any claim to completeness.

Section *A*.

This section includes discussions dealing with a variety of cases of buckling or with cases of a general nature.

DISCUSSION

GEORGE PAASWELL,* M. AM. SOC. C. E. (by letter).—For the first time there is presented before the Society a rational precis of column action, unfortunately, by a mathematical physicist, using the word, unfortunately, in the sense that the language he speaks is foreign to most of his readers. The importance of the subject, as well as of the matter presented, justifies an attempt to annotate the contents of the paper, both as a matter of criticism and as a matter of elucidation to readers interested in column theory.

Fundamentally, the author classifies all column action into three, more or less characteristic, actions: The true buckling—where flexure is the principal action—the author terms "astatic equilibrium"; where distortion is directly proportional to the load, as in the short column, or in ordinary transverse flexure, the related equilibrium is termed "orthostatic equilibrium"; and a mixed condition containing both types of equilibrium is termed "heterostatic equilibrium." Summarized briefly in other terms: Orthostatic, in which $\frac{l}{r}$ is less than 20; heterostatic, in which $\frac{l}{r}$ lies between 20 and 300; and astatic, in which $\frac{l}{r}$ is greater than 300. The values of $\frac{l}{r}$ are, of course, approximate, but are those generally used to distinguish the column types.

Taking up the work presented by the author in the logical order of development, the basis of the analysis is the energy function, the resilience factors as found in a stressed column or thin rod, as the case may be. The development of the work equations may have been predicated on the energy function of Lord Kelvin, with probably more facility in comprehension by engineering readers, but the methods used are undoubtedly better and are the basis of the most modern research in mathematical elasticity.

The voluminous data presented in forming the equations may be necessary from the standpoint of a mathematical physicist—as far as establishing the requisite requirements of rigor—but they are confusing to the engineer. Briefly, the configuration of the elastic curve of columns, slender rods, or thin plates, plane or curved, is determined by a set of parameters, u_m, etc. If the shape of the elastic curve is given by an expression, $y = u \sin a x$, then, any variation in the parameter, u, affects the amplitude of y, but not its phase, exhibiting one character of the parameter.

The equations for work are known to engineers in the form of Castigliano's theorems—the theory of least work and its corollaries following from the well known principle of least action of D'Alembert. Although his theorem should apply essentially to conservative systems,† yet the results may be extended to systems which are not conservative. Astatic systems probably may be regarded as such.

* Cons. Engr., New York City.

† See, for example, Byerly, "Generalized Co-ordinates".

The final useful form of the parameter, as given by Formula (74), follows from the minimum property, and the "effect" which may here be termed the moment, is built up of terms of Formula (74), obtaining the author's fundamental equation. The form as given in Formula (125) involves the introduction of primary eccentricities and, as the author points out, is the basis of most existing formulas.

Proceeding from Formula (74), the formulas of Table 1, and those in Formulas (7) to (10), are established. This should be noted, however. Formula (13) is predicated on very small displacements. The exact expression takes the form:

$$M_n = C_n \, c\,n\,a\,(x + K)$$

where $c\,n$ is the modular cosine, an elliptic function, and characterizes the phenomena grouped under the general term, elastica. For small values, cn becomes a cosine, and $K = \frac{\pi}{2}$, giving the sine form as previously noted. The form, as given, does not lend itself to development in the Fourier series. The higher forms of buckling given by the larger values of n imply necessarily finite displacements, so that the trigonometric series would be in serious error. The modular functions with the values of K adjusted to have the periods fixed by the values of n, gives the more correct forms of the elastica. However, as the coefficients in the Fourier series form a rapidly converging series, the higher terms play no rôle in the analysis, and the equations presented give substantially reliable results.

If one concedes that it is possible to give rational column formulas to cover so-called heterostatic action, the author has completely covered the field of column formulation. The writer will endeavor to show that it is not feasible to establish a formula which will rationally exhibit column action, but that, nevertheless, a mode of procedure does exist, which permits a rational mode of column design.

It may be well at this point to review briefly previous attempts to analyze column action and to see what results have been obtained.

Euler pointed out in 1778 that vertical columns do not break under vertical loads by mere crushing, but that flexure of the column will be found to precede rupture. He proceeded to develop the equations which determine the maximum load to hold a column at a given deflection. Lagrange expressed the limiting load equations in a similar fashion. Robinson* points out that experimental research fails to check Euler and Lagrange. In discussing the results of Hodgkinson's tests, Pearson suggests that there may be some value in the Eulerian hypothesis when it is properly modified so as to include the effect of compression. It is interesting to note here that the analysis of the author shows that when compression is allowed for, the form of the equations in heterostatic action is not changed.

* "A System of Machanical Philosophy", 1805.

E. Lamarle* notes that up to a certain ratio of length to diameter, the maximum load ought to be calculated from the formula:

$$P_0 = \frac{E F S_0}{n}$$

where S_0 is the greatest stretch that can be given without passing the elastic limit; F is the area of the section; and n is Poisson's ratio; the ratio is denoted by K in the paper. Beyond this ratio, the maximum load is given by the Euler expression. It is noted that these expressions seem to reconcile the Euler theory with the existing experimental data.

Rankine proposed the expression bearing his name. He states that this expression was first suggested by Tredgold and afterward revived by Gordon who determined the values of the constant from Hodgkinson's experiments.

A very theoretical study of the action of slender rods is given by Clebsch in his "Theory of Elasticity." The equation of the elastic curve of the rod is determined from the solution of the differential equation:

$$E I \frac{d^2 \phi}{d s^2} = C \sin \phi$$

ϕ is the angle which the tangent to the curve at any point a distance, s, from the terminus makes with any fixed direction. The solution of this equation involves the elliptic functions. An exhaustive analysis of this curve, covering all the higher systems of stability—the higher criteria of astatic equilibrium—has been given by A. E. H. Love, in "A Treatise on the Mathematical Theory of Elasticity," in which an interesting analogy (Kirchoff's analogy) with the motion of a pendulum is illustrated. The question of the elastic stability of systems is also discussed in the text, but, as the rods are slender ones, the treatment is practically that of Euler.

The introduction of the linear law by the late T. H. Johnson, M. Am. Soc. C. E., and the parabolic expression of the late J. B. Johnson, M. Am. Soc. C. E., need not be discussed here, except possibly to quote an excerpt from the paper of Mr. T. H. Johnson,† as follows:

"Before closing this article, it will be well to revert to the older formulas and the reasons why they fail to give satisfactory results * * *. Gordon fell into error, not only from paucity of experiments at his command, but also by following Tredgold's assumption that a certain portion of the area is required to resist flexure. Under this assumption the modulus of compression would remain as a factor in the equation for all length ratios, but with diminishing influence, becoming zero only when $\frac{l}{r}$ becomes infinite: whereas it now appears that the modulus of compression ceases to be a factor when $P = \frac{K}{3}$ [K is the Euler factor] * * *."

In discussing a paper‡ by the late A. J. DuBois, M. Am. Soc. C. E., Mr. T. H. Johnson has hinted at a possible solution of the column theory using

* "Memoire sur la Flexion du Bois", *Annales* des Travaux Publics de Belgique, IV. pp. 1–46 (1846).

† "On the Strength of Columns", *Transactions*, Am. Soc. C. E., Vol. XV (1886), p. 517

‡ "A New Formula for the Strength of Columns", *Transactions*, Am. Soc. C. E., Vol. XXVII (1892), p. 69.

the energy developed as a working basis. This, it is noted, has been accomplished by the author, utilizing the results of modern research, as given in the Bibliography (Part VII).

The rapid growth of column theories and their vague connection with the increasing volume of test statistics made it necessary to draw a distinction between the column of theory and that of practice. Not a sharp or clearly defined distinction, but one sufficient to limit the theory and still provide an opening for empiric adjustment. William Cain, M. Am. Soc. C. E., defines this theoretic column as the "ideal column", and proceeds to effect its theoretic study.* His definition of the ideal column is: "prismatic homogeneous columns, having the force, P, applied at one end, in the direction of the axis or line through the centers of gravity of the cross-sections."

He points out a vital fact in the analysis of the column as carried out by Euler and one which has not been clearly enunciated before, namely, that Euler's formula gives the load at which bending just begins. In this connection, Mr. W. E. Lilley, an earnest and brilliant student of the column, both as a mathematical and as an engineering problem, has demonstrated that Euler's formula considers bending only and ignores the effect of the direct load as a compressive force on the transverse sections.† This, of course, is quite clear from an analysis of the expressions given by the author.

Amplifying the theory of the ideal column, Anson Marston, M. Am. Soc. C. E., has extended the analysis to cover the case of a load of known eccentricity, obtaining the so-called secant expression for the stress.

The converse problem of the "practical column" has been discussed‡ by J. M. Moncrieff, M. Am. Soc. C. E. Intricate expressions were obtained which Professor Cain reduced to the standard secant form.

The results of experiments are always somewhat disappointing. There are, of course, numerous uncertain elements which influence the strength of a column, such as type of form, details, processes of manufacture, fabrication, etc., all of which may not be of calculable nature. The influence of any or all of these elements may be obviated by a wise selection of forms; but this is rarely possible. New tests bring with them new problems to be solved by further experimentation. The ideal function of tests is to supply certain physical constants, which, when substituted in formulas mathematically derived, determine at once the strength factors of a given type of column. Practically, tests fall far short of performing this function and are usually applied as determining the usable stresses in a column of given material and proportions. This is a restricted field for tests, but to the present time they have not justified their extension to broader fields. The late A. P. Boller, M. Am. Soc. C. E., added a discouraging note: "In my opinion no formula will ever give satisfactory results, and dependence must be placed upon experimental charts."

* "Theory of the Ideal Column", *Transactions*, Am. Soc. C. E., Vol. XXXIX (1898) p. 96.

† *Engineering*, July 2d, 1909.

‡ "The Practical Column under Central or Eccentric Loads," *Transactions*, Am. Soc. C. E., Vol. XLV (1901), p. 334.

It is seen that not much progress has been made in the development of column formulas, and this paper may well be taken as a last word in the attempt to formulate column action. At this point, one may well ask "Is a rational column formula possible?"

Briefly, a column is an engineering structure subjected to a compressive force of a determinate character and to a flexure absolutely indeterminate and unpredictive with any mathematical certainty. This, of course, refers to columns presumably axially loaded. The introduction of flexural stresses occurs in a manner which can only form a matter of conjecture. The piece may not be straight due to fabrication, shipping, or erection methods. The loading may not be applied at the geometric axis of the column due to the manner of the connections or other details of the structure of which the column forms a member. The column may be detailed so that the individual shapes comprising the column entity do not act as a unit, so that the distortions under load are not uniform (this is not to be confused with astatic action or equilibrium); or it may be a heavily rolled shape the metal of which does not possess uniform elastic properties.

In a number of cases, where there is a transverse load, or where known moments are introduced at the column ends, it is possible to predict the flexure with reasonable accuracy. For the present, the standard column type—an independent structural unit—is under discussion. Tests serve a general purpose in giving clues to column action, but like theory itself, they must be interpreted with a clear apperception of the physical improbability of defining column action rigorously.

Emphasizing the fact that despite elaborate analysis, there is no way of determining the flexure moment of what may be termed simple heterostatic action, that is, no transverse loading, it seems inevitable that one must answer the leading question, "Is a rational column formula possible?" in the negative. Since some method of analysis is necessary, the proper mode of procedure would seem to be, to find out under what conditions, referring, of course, to unique cases, the value of the moment, M, can be made determinate.

Stated in slightly different language, the problem for each individual case examined seems to be to learn just what is the true position of the applied load. This eccentricity would lead to the selection of the proper formula, as given by Professor Westergaard, or to some of the simplifications now in vogue. Again, in a number of cases, it is possible to determine just what moment is introduced into the column by its adjoining members. If such moment is calculable, it is the moment to be used in the general formula.

The column is usually treated as a separate and distinct unit taking its load, presumably axial, but no other stress, from its neighboring units. This is the ideal, but far from the actual, condition. Every structural member, whether beam, column, or only a connecting detail, is a part of a system of framework, and it is through the distortion of the frame by various types of loading that the several members, comprising the frame, are stressed. By a study of the frame itself, therefore, it may be possible to make determinate the factor, M, in the column formula. A few examples may illustrate the possibilities of this mode of analysis.

The simple bent, as shown in Fig. 15, is a common type of construction, and usually the girder is assumed to rest lightly on the column, that is, it is designed as a simple beam with free supports. On the other hand, the designer may purposely introduce such details as will fix the corner, making it rigid, thus transferring a moment into both the column and the girder. It is possible, of course, that in the actual case such details will be used as will develop a joint intermediate between the free and the fixed ones, the designer assuming a simply supported beam and a column taking no moment from the joint.

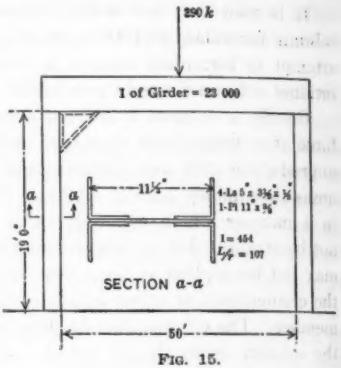

FIG. 15.

It is important to note that the joint, as a simple connection, places no restraint on the deflection of the girder and the girder must throw a substantial, if not the entire, portion of its load on the inner edge of the column. One may safely assume that the entire load will thus be placed. The eccentricity of the load is thus measurable and M can be determined. Assign arithmetical values to the members shown in Fig. 15. The value of the moment is $185 \times 0.48 = 89$ ft-kips. Following the method ordinarily used and obtaining the permissible stress from the building code formula of New York City,

$$\left(p = 15\,200 - 58\,\frac{L}{r}\right)$$

the allowable unit stress is 9 000 lb. per sq. in., which the area and slenderness ratio of the column just satisfy. Using the formula:

$$F = \frac{P}{f} + \frac{M_c}{I}$$

and taking an allowable stress for f of 16 kips per sq. in., and with the other functions of the section as noted in the diagram, solving for M, there is found a value of 45 ft-kips., only half the moment as determined from the eccentric location method. Although it is true that one may say that the entire concentration of the load on the column edge is only a matter of conjecture, it is a possible and, more emphatically, a probable condition and gives a calculable premise which is a vital point in rational and consistent design.

Take an alternative condition: The joint is made a fixed one, thus bringing the girder reaction concentric with the column section. Assume that the girder is loaded, as shown in Fig. 15, with a single concentration at its midpoint. Computing the moments from *Bulletin No. 108,* University of Illinois, "Analysis of Statistically Indeterminate Structures by the Slope Deflection Method," by Messrs. Wilson, Richart, and Weiss, on the assumption that the detail fixing the joint is dimensioned so that it reinforces the column section to a point 2 ft. below the girder, it is found that the column section must

be such as to carry a moment of 160 ft-kips. Clearly, it is not enough merely to call a joint fixed. It must be made so, and the column must be designed to meet the moment. On the other hand, if a detail is introduced which, in effect, fixes the connection, care must be taken to see that the column can safely take the moment induced. The writer is aware that this question is amply covered in most treatises on secondary stresses, but it is quite doubtful whether, in ordinary structural design of simple frames, the effect of the joint is properly examined. As a matter of comment, however, it seems safe to say, that, in this case, also, it is possible to compute a value of M and that resort to a column formula is unnecessary.

Several other cases might be mentioned, such as building columns, framing between girders, viaduct columns, and columns which are subjected to a definite transverse load, such as subway columns and the like. Many more types will undoubtedly occur to the reader. It is sufficient to state that, in engineering practice, in the majority of cases, it is possible to find a calculable moment in the column member.

The column formula is predicated on an uncertain flexure, while it has been noted that it is possible to observe the moment to which the ordinary column is subjected. It seems, therefore, a rational method of design to make provision for the stresses which can be directly computed, using such permissible unit stresses as tests on short compression blocks exhibit, or tension tests, since these give about the same result as the compression tests. It may be objected that this method of design ignores the true column action induced by the accidents of fabrication or erection. This objection, although a valid one, may be applied to all structural units. If correct analysis has been used in developing a section to fit into a given structure, with proper provision for flexure, where such flexure can be calculated, the accidental stresses must be assumed to be taken care of in the factor of safety.

This method demands great alertness on the part of the designer. The deformations of the entire structure of which the column forms only one unit must be carefully studied. The standard column formula is a blanket allowance for all such uncertain loadings. The rational method suggested gives the designer no such royal path to a simple design. It is a postulate of good engineering design that the details should fully develop the structural members which they interconnect. The converse of this may now well be emphasized. Structural members should be designed to carry safely the stresses which the details bring to them. Too often this is not done. There is too much child-like faith in "axial loads", "free supports", etc. It is true that in monumental structures a correct apperception of the conditions is had, and the details and the main sections are designed with consistency; but this is not so in structures of every-day design. Joints are made fixed by heavy details to secure a rigid structure, while the individual members are treated as separate and distinct units.

Two conditions may form an exception to the suggested method of design. Cases may occur where, as far as a thorough study can determine, a column is axially loaded with no outside induced flexure. As this is the type of column which is usually tested, it may be safe to say that column formulas

predicated on tests of similarly formed columns are rational ones to use. The results of Professor Westergaard's investigations indicate that the Rankine expression is well founded*. In this connection, it may not be amiss to state that a series of tests on framework would give more profitable results than tests on columns alone.

The second exception is an important one. Throughout the author's analysis, and in engineering design in general, the metal is assumed to have uniform elastic properties. The heavy rolled sections do not possess such uniformity, and low ultimate and low useful limit points are found in columns assembled with heavy shapes. The use of metal of this character will give a section of low average resistance in comparison with a section of the same area, but composed of lighter shapes. For this condition, a study of the report of the Special Committee on Steel Columns and Struts† will indicate just what should be used in the way of safe stresses. This exception, where there is a way of calculating a flexural stress, merely affects the total permissible stress, the proper formula to be used being in no way affected by the fact that the ultimate stress is lower than that found for thin rolled sections.

One may say in conclusion that, although it does not seem possible to discover a rational column formula, a rational method of column design does exist, but that a more detailed study of the structure is required than is ordinarily given. This objection, however, cannot be considered a libel against the method suggested. In the choosing of a column section, only half the problem is solved. The column details are vital, possibly more vital than the selection of the section members, as disastrous failures have indicated. A rational mode of design permits a rational mode of detailing. A well-knit consistently designed and detailed column contains a far greater factor of safety, even though the accidental stresses usually attributable to so-called column action have been neglected, than the column designed in accordance with some of the numerous formulas, with the vague rule-of-thumb methods of proportioning the details.

EUGENE E. HALMOS.‡ M. AM. SOC. C. E. (by letter).—This paper is probably the most thorough treatise that the writer has seen on the theory of combined buckling and "cross-bending" of columns and slabs. The general theory applicable to other structural forms, so interestingly demonstrated, will also be appreciated by all students of mechanics of structures. The author is to be commended for indicating and illustrating the extreme usefulness of one of the best tools of higher mathematics, the Fourier series, in the solution of problems encountered in engineering design.

It is gratifying to note that the author has proven the formulas in general use for designing columns (Formulas (1), (2*a*), and (2*b*)) to be on the safe side

* See, also, "A Review of Column Formulas for Bridge Design", *Engineering News-Record*, March 10th, 1921, p. 431, etc. The suggested formula is:

$$p = \frac{16\,000}{1 + \frac{L^2}{18\,500\,r^2}}.$$

† *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–20), p. 1583.

‡ Designing Engr., Parsons, Klapp, Brinckerhoff and Douglas, New York City.

by a considerable margin, except in the case of fixed end columns and distributed side loads (Case IV, Formula (5)). However, as designers will dimension the columns on the basis of maximum transverse moment, which, in the case of a fixed beam, occurs at the ends, it will be seen, by comparison with the author's Formula (6), that the use of the "approximate" formulas results in safe structures.

All the author's examples refer to the particular cases where "orthostatic" loading increases the effect of "astatic" action. There is, however, a case, often met in practice, where the opposite is true, namely, an upright thin cylinder or drum supporting a vertical load and being filled with a gas or liquid exerting a greater pressure on the wall than that of the surrounding air or liquid. The writer proposes to show the derivation of formulas for such a "heterostatic" loading. A slightly modified presentation of Professor Forchheimer's solution, published in a little known pamphlet,* will be given. First, the equilibrium conditions of a cylindrical drum supporting only a vertical load will be derived, and then the influence of inside and outside pressures will be demonstrated.

A.—Buckling of an Upright Thin Cylinder Under a Load Distributed Along the Rim.—Quoting the author, "a thin cylindrical shell or tubular strut may buckle into a double-curved surface under the influence of a compressive load parallel to the axis" (page 580). This form of failure will be treated by the writer, not the assymetrical buckling investigated by R. Lorenz in his paper referred to in the author's Bibliography, Part VII, Section *H*.

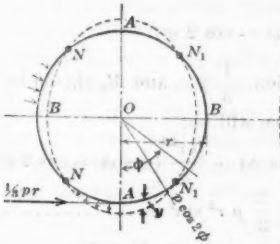

FIG. 16.

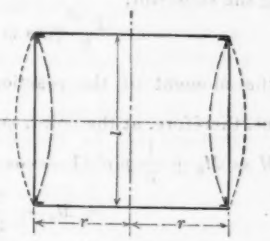

FIG. 17.

In Fig. 16, let the circle drawn in full line represent the horizontal section of a vertical drum stiffened on top and bottom, the radius, r, being assumed to be large compared with the thickness of the shell, and let the dotted elliptical line be the same section after the drum has deformed under the influence of a compressive load distributed uniformly over the rim of the cylinder. Fig. 17 is a vertical section of the shell, the full lines representing the unstressed wall of a perfect cylinder, the dotted lines the deformed wall along Diameter *A-A*, and the dashed lines the deformed wall along Diameter *B-B*. If it is assumed that the shell consists of a large number of independent vertical strips, it is evident that, should a horizontal thin band be welded around the drum, this band would be pushed radially outward between the nodal points, *N N'*, and radially inward between the points, *N N*, and *N' N'*, by

* "The Berechnung Ebener und Gekrümmter Behälterböden", 1909.

forces proportional to the distance of the elliptical contour from the original circular one (Fig. 16).

Consider a ring of unit height, sectional moment of inertia, I, modulus of elasticity, E, subjected to forces of the character described. Denoting with p the (unknown) maximum pressure intensity, the unit pressure at any point of the ring can then be expressed by,

$$p \cos 2\phi = p\ (2\cos^2\phi - 1)$$

in which ϕ is the angle between the vector and the radius, $O\ A$.

At A, where $\phi = 0$, we have a reaction:

$$p\,r\int_{-\frac{\pi}{2}}^{0}(2\cos^2\phi - 1)\sin\phi\,d\phi = p\,r\left[\frac{-2\cos^3\phi}{3} + \cos\phi\right]_{-\frac{\pi}{2}}^{0} = \frac{p\,r}{3} \quad ..(162)$$

and a moment, M_0, yet unknown.

At the point where $\phi = \phi_1$, the moment of all pressures between 0 and ϕ_1, will be:

$$\int_0^{\phi_1} p\,r\,(2\cos^2\phi - 1)\,r\sin(\phi_1 - \phi)\,d\phi^*$$

$$= p\,r^2\sin\phi_1\int_0^{\phi_1}(1 - 2\sin^2\phi)\cos\phi\,d\phi - p\,r^2\cos\phi_1\int_0^{\phi_1}(2\cos^2\phi - 1)\sin\phi\,d\phi$$

$$= p\,r^2\sin\phi_1(\sin\phi_1 - \frac{2}{3}\sin^3\phi_1) + p\,r^2\cos\phi_1\left(\frac{2}{3}\cos^3\phi_1 - \cos\phi_1 + \frac{1}{3}\right)$$

$$= \frac{p\,r^2}{3}(-2\cos^2\phi_1 + \cos\phi_1 + 1)$$

or, dropping the subscript,

$$\frac{p\,r^2}{3}(\cos\phi - \cos 2\phi)$$

to which the moment of the reaction, $\frac{1}{3}\,p\,r$, and M_0 should be added. The total moment, therefore, at the point, ϕ, will be:

$$M = M_0 + \frac{1}{3}\,p\,r^2(1 - \cos\phi) + \frac{p\,r^2}{3}(\cos\phi - \cos 2\phi)$$

$$= M_0 + \frac{2}{3}\,p\,r^2\sin^2\phi \quad .....(163)$$

According to Boussinesq,† the deformation of a ring generally follows the law:

$$y + \frac{d^2y}{d\phi^2} = \frac{M\,r^2}{I\,E} \quad ..... (164)$$

Substituting the value of M from Formula (163), we have the differential equation:

$$\frac{I\,E}{r^2}\left(y + \frac{d^2y}{d\phi^2}\right) = M_0 + \frac{2}{3}\,p\,r^2\sin^2\phi$$

the integral of which is:

$$\frac{I\,E}{r^2}\,y = M_0 + \frac{2}{9}\,p\,r^2(1 + \cos^2\phi) + C_1\sin\phi + C_2\cos\phi$$

* The change in the length of r, due to the deformation of the shell, is neglected. This is permissible because this deformation, compared with the radius (which is assumed to be large), is very small before failure occurs. Consequently, the forces, $p\cos 2\phi$ are also small.

† *Comptes Rendus*, Vol. 97 (1883) p. 843.

in which C_1 and C_2 are the constants of integration.

By hypothesis (Fig. 16):

$$\frac{I\,E}{r^2}\frac{d\,y}{d\,\phi} = -\frac{4}{9}\,p\,r^2 \sin\phi\cos\phi + C_1\cos\phi - C_2\sin\phi$$

must vanish for both $\phi = 0$ and $\phi = \frac{\pi}{2}$, making $C_1 = C_2 = 0$, and,

$$\frac{I\,E}{r^2}\,y = M_0 + \frac{2}{9}\,p\,r^2(1+\cos^2\phi) \ldots\ldots\ldots\ldots\ldots\ldots (165)$$

M_0 can now be solved by applying the condition that the length of the circumference of the ring remains unchanged when the shell is deformed, that is,

$$\frac{I\,E}{r^2}\int_0^{\frac{\pi}{2}} y\,d\,\phi = \left[M_0\,\phi + \frac{1}{9}\,p\,r^2(3\,\phi + \sin\phi\cos\phi)\right]_0^{\frac{\pi}{2}} = 0$$

$$M_0 = -\frac{1}{3}\,p\,r^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (166)$$

which value, substituted in Formula (165), results in

$$y = \frac{p\,r^4}{9\,I\,E}(2\cos^2\phi - 1) = \frac{p\,r^4}{9\,I\,E}\cos 2\,\phi \ldots\ldots\ldots\ldots (167)$$

representing the deformation of a ring radially loaded with forces, $p \cos 2\,\phi$.

Consider, now, a vertical strip of the drum shell, of unit width and length (or height) l, which buckles under a load, Q. Such buckling will be resisted by the horizontal rings with forces proportional to the deformation of the vertical strip. It is assumed that the cylindrical wall of the drum is able to turn freely (in other words, is hinged) at the top and bottom about the stiffening rings. From the theory of buckling of columns, it follows that the strip will deform into a half wave of a sine curve (Fig. 18), and, denoting by q the maximum intensity of the resistance exerted by the rings, the unit pressure resisting the buckling at a height, x, above the base of the strip is given by:

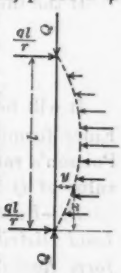

FIG. 18.

$$q \sin\frac{\pi\,x}{l}$$

The reactions at the top and bottom of this strip, corresponding to these horizontal forces, will be:

$$\int_0^{\frac{l}{2}} q \sin\frac{\pi\,x}{l}\,d\,x = \left[-q\,\frac{l}{\pi}\cos\frac{\pi\,x}{l}\right]_0^{\frac{l}{2}} = \frac{q\,l}{\pi} \ldots\ldots\ldots (168)$$

The total moment at the point, x_1:

$$M = Q\,y + \int_0^{x_1}(x_1 - x)\,q \sin\frac{\pi\,x}{l}\,d\,x - \frac{q\,l}{\pi}\,x_1 = Q\,y$$

$$-\left[q\,x_1\,\frac{l}{\pi}\cos\frac{\pi\,x}{l} - q\,\frac{l}{\pi}\,x\cos\frac{\pi\,x}{l} + q\,\frac{l^2}{\pi^2}\sin\frac{\pi\,x}{l}\right]_0^{x_1}$$

$$-q\,\frac{l}{\pi}\,x_1 = Q\,y - q\,\frac{l^2}{\pi^2}\sin\frac{\pi\,x_1}{l} \ldots\ldots\ldots\ldots\ldots (168a)$$

With the notation used, the differential equation of the elastic line becomes,

$$I\,E\,\frac{d^2\,y}{d\,x^2} = -\,Q\,y + q\,\frac{l^2}{\pi^2}\sin\frac{\pi\,x}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots (169)$$

the solution of which, considering that y must vanish for both $x = O$ and $x = l$, can be written as:

$$y = \frac{q\,l^4}{\pi^2\,Q\,l^2 - \pi^4\,I\,E}\sin\frac{\pi\,x}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots (170)$$

Now, by hypothesis,

$$p\cos 2\,\phi = q\sin\frac{\pi\,x}{l}$$

and y in Formulas (167) and (170) is identical, therefore,

$$\frac{r^4}{9\,I\,E} = \frac{l^4}{\pi^2\,Q\,l^2 - \pi^4\,I\,E}$$

from which the critical load which can be supported on the unit length of the rim of a thin cylinder of given r, l, I, and E, is:

$$Q = \frac{\pi^2\,I\,E}{l^2}\left(1 + \frac{9\,l^4}{\pi^4\,r^4}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (171)$$

If the thickness of the shell is t, then $I = \frac{t^3}{12}$, and Formula (171) becomes,

$$Q = \frac{t^3\,E}{l^2}\left(0.822 + 0.076\,\frac{l^4}{r^4}\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots (171a)$$

It will be noted that for $r = \infty$, Formula (171) reverts to the well known Euler formula for columns hinged at the top and bottom. The influence of Poisson's ratio was neglected in the derivation of Formula (171), so that the value of Q is slightly on the safe side.

B.—Buckling of an Upright Thin Cylinder Under a Load Distributed Along the Rim and Supporting a Uniform Radial Inside Pressure.—The ring of unit height previously considered is assumed to support inside radial forces of constant intensity, p_1, the magnitude of which is large compared to $p\cos 2\,\phi$. This inside pressure results in a ring tension, $T = p_1\,r$, tangent to the original circular contour and, therefore, acting with a lever, y, on the displaced elements of the deformed ring, Fig. 19. The moment equation, Formula (163), therefore, changes to:

FIG. 19.

$$M = M_0 + \frac{2}{3}\,p\,r^2\sin^2\phi + T\,y \quad \ldots\ldots\ldots\ldots\ldots\ldots (172)$$

and the differential equation of the elastic line to:

$$\frac{I\,E}{r^2}\left(y + \frac{d^2\,y}{d\,\phi^2}\right) = M_0 + \frac{2}{3}\,p\,r^2\sin^2\phi + T\,y \quad \ldots\ldots\ldots\ldots (173)$$

Noting that $\frac{d\,y}{d\,\phi}$ vanishes for $\phi = 0$ and $\phi = \frac{\pi}{2}$, as seen in Fig. 19, the

integral of Formula (173) can be written as:

$$y = \frac{r^2 M_0}{I E - T r^2} + \frac{4}{3} \frac{I E p r^4}{(I E - T r^2)(3 I E + T r^2)} - \frac{2}{3} \frac{p r^4 \sin^2 \phi}{3 I E + T r^2} \quad (174)$$

which can be readily proven by forming $\frac{d^2 y}{d \phi^2}$ and substituting this and the expression for y in the left-hand member of Formula (173).

The condition that the length of the quadrant remains unchanged will give the value of M_0:

$$\frac{I E - T r^2}{r^2} \int_0^{\frac{\pi}{2}} y \, d \phi = M_0 \frac{\pi}{2} + \frac{4}{3} \frac{I E p r^2}{3 I E + T r^2} \frac{\pi}{2} - \frac{2}{3} \frac{I E - T r^2}{3 I E + T r^2} \frac{\pi}{4} p r^2 = 0$$

from which, as before,

$$M_0 = -\frac{1}{3} p r^2$$

and, finally,

$$y = \frac{1 - 2 \sin^2 \phi}{3 (3 I E + T r^2)} p r^4 = \frac{p r^4}{3 (3 I E + T r^2)} \cos 2 \phi \quad \ldots\ldots (175)$$

Formula (175) holds simultaneously with Formula (170),

$$y = \frac{q l^4}{\pi^2 Q l^2 - \pi^4 I E} \sin \frac{\pi x}{l}$$

in which, again, $q \sin \frac{\pi x}{l}$ is identical with the forces, $p \cos 2 \phi$, developed in the ring and resisting distortion; the inside pressure, p_1, is in equilibrium with the tangential tension, T. Therefore, eliminating y between Formulas (170) and (175), and solving for Q, we obtain:

$$Q = \frac{\pi^2 I E}{l^2} \left(1 + \frac{9 l^4}{\pi^4 r^4}\right) + \frac{3}{\pi^2} \frac{l^2}{r^2} T \quad \ldots\ldots (176)$$

indicating, by comparison with Formula (171), the substantial increase in the critical load which can be supported on the rim of a drum when inside pressure is acting.

In terms of the thickness of the wall:

$$Q = \frac{t^3 E}{l^2} \left(0.822 + 0.076 \frac{l^4}{r^4}\right) + 0.304 \frac{l^2}{r^2} T \quad \ldots\ldots (176a)$$

C.—Buckling of an Upright Thin Cylinder Under a Load Distributed Along the Rim and Supporting a Uniform Radial Outside Pressure.—An outside pressure of intensity, p_2, will produce a tangential compressive force, $P = p_2 r$, in the ring. The critical load which can be supported by the drum, by the same reasoning as demonstrated, in Section *B*, can be written as:

$$Q = \frac{\pi^2 I E}{l^2} \left(1 + \frac{9 l^4}{\pi^4 r^4}\right) - \frac{3}{\pi^2} \frac{l^2}{r^2} P \quad \ldots\ldots (177)$$

or, in terms of the thickness of the shell,

$$Q = \frac{t^3 E}{l^2}\left(0.822 + 0.076\,\frac{l^4}{r^4}\right) - 0.304\,\frac{l^2}{r^2}\,P \ldots\ldots (177a)$$

This formula shows the substantial decrease in the supporting power of a drum or tubular strut when under outside pressure, and it also shows that buckling may occur even though no vertical load is applied, if,

$$P = \frac{\pi^4\, I\, E\, r^2}{3\, l^4}\left(1 + \frac{9\, l^4}{\pi^4\, r^4}\right)$$

or,

$$p_2 = I\, E\left(\frac{3}{r^3} + \frac{\pi^4\, r}{3\, l^4}\right) \ldots\ldots (178)$$

and, in terms of the thickness of the shell, if,

$$p_2 = \frac{t^3\, E}{r^3}\left(0.25 + 2.706\,\frac{r^4}{l^4}\right) \ldots\ldots (178a)$$

A cylinder of length, l, without stiffening rims, must behave in the same manner as one infinitely long with stiffened ends; substituting $l = \infty$ in Formula (178), we get, for the buckling load of cylinders with outside radial pressure,

$$p_2 = \frac{3\, I\, E}{r^3} \ldots\ldots (179)$$

which simple formula was first given by Boussinesq.*

EDWARD GODFREY,† M. AM. SOC. C. E. (by letter).—This paper enriches the science of column mathematics with new formulas and new views as well as new terms. The writer believes it is a legitimate criticism of the paper to state that it does not offer much help to the practical designer. Only a few men in the Profession, outside of the colleges, will be able to follow this paper or even to understand and use the formulas derived.

The writer has searched the paper for a formula that would give the theoretical collapsing pressure on a thin tube subjected to external pressure, but could not find it, although the Synopsis holds out the promise that this problem, among others, is solved.

As an example of the problem that faces the designer, take Table 2, in which the relation between the total moment on a column subject to bending to the moment from bending alone, is given. Here, one finds that a certain fraction of the Euler load exerted endwise on a column, will increase by a definite ratio any moment due to lateral loads, regardless of what the moment from lateral load may be. To know this is useful if it has application in a practical design, but what the designer wishes to know is, what end load or what side load may be allowed against a column and still be safe in the design. He also wishes to know to what class of columns Table 2 should be applied.

For example, if a factor of safety of 5 on the Euler load is used in the case of a hinged-end column with a center side load, the moment due to the

* *Comptes Rendus*, Vol. 97 (1883), pp. 844 and 1131.

† Structural Engr. (Robert W. Hunt and Company), Pittsburgh, Pa.

side load will be increased 20 per cent. Will the column be safe? Or, suppose the column is slender and a factor of safety of 1.8 is considered sufficient, the end load will double the moment from the side load, regardless of what that moment may be. European engineers use the Euler formula for designing columns with a factor of safety of 5. In America many long derrick booms are designed, that have an actual factor of safety of 1.5 or 2, and the weight of the boom furnishes the lateral load; or the dead end of the boom line may be attached to the middle of the boom, and the upward force may exceed the boom weight.

Between these two extremes, there must be a medium that represents safe and economic design. The European practice of using the Euler formula with a factor of safety of 5 cannot be defended, because the Euler formula does not give even an approximation of the ultimate strength of permissible structural columns, and a factor of safety of 5 for slender columns, where the Euler load does apply, is entirely too large and results in a waste of material.

As the author points out, there is not a start of failure in a slender column until the Euler load is nearly reached. Why, therefore, should there be such a wide margin between the working load and the ultimate? In permissible structural columns there is actual unit stress which is a good fraction of the actual elastic limit of the metal, therefore, the factor of safety should be of some magnitude to take care of overload and of the so-called fatigue of the metal. In slender columns, the actual unit stress under a factor of safety of 5 may be as little as one-fiftieth of the elastic limit or less. This is one of the cases pointed out by Professor Westergaard, where increased load and increased deflection are not directly proportional. There is a sudden jump to the ultimate.

It is of the utmost importance that designers should be familiar with the following facts concerning column design, namely, the inapplicability of slender column formulas to short columns and the equal inapplicability of formulas for short columns to the design of long columns. The author does not distinguish between short and long columns, nor does he state that the formulas given have an application chiefly, if not solely, to slender members. Increased deflection in slender columns gives rise to increased bending moments due to the endwise load. In admissible structural columns, however, the deflection due to externally applied loads is small.

The author does not recognize nor provide for imperfections in columns. In the writer's judgment, no treatment of the strength of columns can be of definite value, which does not recognize the fact that columns are imperfect, and the imperfections have a great influence on their strength. Perfect columns, perfectly loaded, would have a strength greatly in excess of commercial columns loaded in the manner feasible in practice; this refers to structurally permissible columns and not to slender members. Furthermore, the nature of the imperfection assumed must be possible or one that can be defended.

The Gordon formula for columns is based on the assumed imperfection of the column. The imperfection is a bow or deflection in the column directly proportional to the square of the length and inversely proportional to the depth of the column cross-section, and this imperfection is "frozen" in the

column, that is, increased deflection due to application of the end load is ignored. Let these assumptions be examined. For example, suppose a column is 5 ft. long, has an offset of 0.2 in., or $\frac{1}{300}$ of the length. This column might pass for straight. Now, take a column of the same cross-section, 50 ft. long; to agree with the Gordon formula the deflection would be 100 times as great, or 20 in. This column would be bowed, and the imperfection would be so great that the case would not be classed as simple column action. In this case, what the author points out as being true in some cases, namely, that stress is not proportional to load, is of prime importance.

A coefficient determined by test on a short column, for insertion in the Gordon formula, would give a value based on compressive strength of the steel, and elasticity or buckling of the column as a whole, would have little effect; whereas a coefficient for a slender column would be controlled entirely by the elastic properties of the steel, the properties beyond the elastic limit having no effect whatever. Obviously, no agreement could possibly exist between these two columns that a formula of the Gordon type could reconcile.

A great deal of the column mathematics is useless, because it fails to recognize column facts and deals solely with the theory of the ideal column. Any chart of tests on columns will show that a definite column formula for the ultimate strength of a column is impossible. The wide variation between test results of columns of similar properties is the proof of this.

The writer has published* a paper on the strength of columns, which, in effect, gives a rational derivation of the straight-line formula. The formula derived, although complex, has a locus that coincides almost exactly with the commonly used straight-line formula for ratios permissible in structures. The only assumptions are that the unit stress on the extreme fiber of the column is 16 000 lb. per sq. in. and that the column is imperfect. The imperfection is a bow in the axis of the column, the offset being $\frac{1}{300}$ of the column length. Increased deflection due to endwise load is taken into account, as the author has done in his investigations. This article is re-printed in the writer's book, "Steel Designing", and is believed to be the only attempt to demonstrate the straight-line formula as a rational formula. The author apparently did not consider this paper of sufficient merit to mention it in his Bibliography. It would seem that a demonstration of the rationality of the one formula used generally in America for columns, would be worthy of recognition if only to prove its falsity if it is falsely derived. It is just as important to point out the errors of the literature on the subject as to emphasize the merits.

In the Synopsis of the paper, the fact is recognized that a straight, homogeneous and elastic column will reach a point where it bends out suddenly. This is called the critical value. In the body of the paper, it is shown that this point of sudden bowing is the Euler load. In the Introduction, it is stated:

"The neutral equilibrium, maintained at this constant critical load throughout a continuous range of increasing deflections, is the criterion of pure buckling. The load may be increased beyond the critical value at which the bending ordinarily begins, and still the column may be made to remain in equilibrium in an undeflected state."

* *Railway Age Gazette*, July 2d, 1909.

The condition of a column at the Euler load, the author calls a "stable neutral equilibrium."

With this quotation from the Introduction, and with the idea that a column at the Euler load is in a stable neutral equilibrium, the writer cannot agree. It is of great importance that it be made clear that at the Euler load a column has reached its absolute ultimate load and is not in any kind of equilibrium. That a column is in equilibrium at the Euler load carries with it the idea of reserve strength, but it can be proven by mathematics that the Euler load is the ultimate load that a column can sustain.

The common derivation of the Euler relation finds that for any assumed deflection, the column remaining elastic, there is theoretical equilibrium between the internal resistance and the applied load. From this, it is asserted that the column is capable of sustaining the Euler load at any assumed deflection. The truth is that this is merely the history of the failure of the column. When the Euler load is reached, the column begins to deflect measurably, and continues to deflect without increased load. Nothing could prevent the continuance of this deflection, after it is once started, unless it should be some other means of support for the load, and this is not admissible. There is nothing, therefore, to prevent the failure of the column.

The proof, referred to is this: Assume a column with hinged ends and having a bow with an infinitesimal offset—a straight column, mathematically speaking. Let the curve of this assumed bow be a sine curve. Calculate the endwise load that will double the assumed infinitesimal bow, which load will double the bow an infinite number of times, and is the Euler load. This multiplication of the infinitesimal deflection means a finite deflection and failure. Thus, by an absolute proof, the column is shown to have reached its ultimate load. There is no room here for the conception of equilibrium.

The author asserts, however, that the column may assume a curve made up of a number of half-waves instead of one curve, which would mean that the column is perfectly regular in its imperfection, and would possess a tendency to bow in one direction for a segment of its length and in the other direction in the next segment, and so on throughout its length. The points of inflection would have to be the same distance apart, and that distance, an exact multiple of the column length. The deflected segments would have to deflect the same amount, otherwise, there would not be a balance between the several segments at points of inflection, which would set up unbalanced forces and cause lateral motion. There is nothing in the nature of columns to warrant the assumption of such impossible conditions.

The author states in the quotation given previously that the column may be made to remain in equilibrium in an undeflected state with the load beyond the critical value at which the bending ordinarily begins. If this means that the column may be made to carry more load by supplying lateral support, it is immediately placed in another class, where the formula has no application. In fact, there is no other way to make a column that has reached the Euler load, carry any more load, except by supporting the column laterally, and thus vitiating the formula as regards that column.

The writer finds that few designers have any conception of the strength of slender columns and of the application of the Euler formula to the proportioning of columns. The reason for this is doubtless the character of the common mathematical treatment in books and in papers on columns. Another thing that has a great influence in the same direction is emphasis on the formulas and tests for structurally permissible columns. All of it may be summed up in the failure of writers to differentiate between slender and short columns, the failure to point out clearly the difference between their action under load, and also that in the zone where slender and short columns meet or overlap, the characteristics of each action must be properly considered and combined.

Mathematical writers have been too assiduous in their quest for a perfect column formula. Nothing but a perfect column would approximately measure up to their formula, particularly in a structurally permissible column.

The "whip formula", presented in the writer's book, comes about as near passing through the middle of any group of tests as any curved-line formula in use. As the handle of the whip, or the straight portion, is the only part that concerns structural designers, it is eminently proper that a simple straight-line formula should be used for structural members. An example of how column tests group themselves around a straight line has been given.*

Designers of airplane struts and transmission towers deal with slender columns, and it is important that their characteristics should receive the attention of the Profession. Only recently the writer's attention was called to designs of transmission towers where high unit stresses were used in columns because of the special quality of the steel. Theory demonstrates that in slender compression members, carbon steel has little or no advantage over soft steel, as the modulus of elasticity is the only factor affecting the results. Tests also demonstrate the same thing.

The writer is unable to understand the author's formulas for square slabs supported on four edges. On page 600, the intensity of the moment of such a slab is given as $0.042\ wb^2$. In other places, for example, Formula (36), it is given as $0.077\ wb^2$. Still another value, on page 599, works out as $0.037\ wb^2$ for a square slab.

On page 599, it is stated that in a slab that is square or nearly square, greater moments occur along and across the diagonals at the corners than at the center. How can a slab be subject to bending when and where it is in contact, by hypothesis, with a rigid and straight support? At the corners, the slab is in contact with the supports, and could not bend either in the direction of the diagonal or transverse with it. Surely no one would reinforce a slab against bending in the corner, where there could be no deflection whatsoever and, therefore, no stress on the reinforcement. If any conceivable force could split the slab in the corner, diagonally, or pinch off the corner, what measurable effect would it have on the slab as a whole?

In the Bibliography, the author has neglected to mention some useful and practical tests on the collapsing pressure of tubes subject to external pressure, which tests† were made by Mr. R. T. Stewart, of the University of Pittsburgh.

H. M. WESTERGAARD,* ESQ.† (by letter).—The scope of the writer's investigation was defined so as to exclude the cases in which the deflections are large and those in which the stresses exceed the proportional limit. The first limitation excludes the consideration of the very slender structures the deformations of which have developed beyond the initial stage. The second limitation excludes the application of the method to the exact analysis of the heavier structures at the ultimate load, which cannot be reached until the proportional limit has been exceeded. The phases of the subject thus excluded, are essential in a complete study of column action. For example, the action of short or medium-long columns cannot be appreciated fully without taking into account the behavior of the material beyond the proportional limit; concerning this matter, reference is made to the works of Kármán, Southwell, and Salmon.‡

By limiting the field, however, it became possible to develop an analysis which applies to structures of many shapes; and if the inevitable initial eccentricities are taken into account, as in Articles 24 to 26 of the paper, this analysis will explain quite accurately the strength properties, not only of slender, but also of medium slender structures, for example, of medium slender columns. Rankine's formula is shown in this way to apply with rough approximation to the buckling of columns and of certain other structures (see the closing paragraph in Article 26).

Mr. Paaswell has mentioned slender columns with deflections so large that Euler's theory must be replaced by a more general theory of the elastica. This case, strictly speaking, is outside the scope of the investigation, but the results of an exact analysis of it may be used to decide how large the deflections of a column may be before the deviations from Euler's theory become appreciable. A formula given by Schneider,§ as a result of the exact analysis, is quoted: The end load on a hinged-ended column is:

$$P = \frac{\pi^2 E I}{L^2}\left(1 + \frac{1}{8}\left(\frac{\pi}{L}\right)^2 f^2 + \frac{19}{512}\left(\frac{\pi}{L}\right)^4 f^4 + \frac{29}{2048}\left(\frac{\pi}{L}\right)^6 f^6 + \cdots\right)$$

where L is the length measured along the elastic curve (slightly shortened by the axial force) and f is the maximum deflection. When $\frac{f}{L} = \frac{1}{10}$ the load, P, differs from Euler's value only by about 1.25%; that is, with a maximum deflection equal to as much as one-tenth of the length, Euler's theory still gives a close approximation.

In making applications of the analysis to the initial stages of flexure of the very slender structures, the possible influence of the weight of the structure must be carefully considered. For example, according to Euler's formula for hinged-ended columns, a steel blade, 0.025 in. by 1.5 by 36 in. (with $\frac{l}{r} = 5\,000$), would support an end load equal to 0.45 lb., but, as the blade

§ Alois Schneider, "Zur Theorie der Knickfestigkeit", *Zeitschrift* des Oesterr. Ing.- und Arch. Vereines, Vol. 53 (1901), pp. 633–638, 649–653, in particular, p. 638.

weighs 0.38 lb., Euler's theory cannot be applied unless the blade is placed in a horizontal position, on edge. Placed in a vertical position, with simple supports at the ends, the blade would buckle under the influence of its own weight when a small end load is added, but the elastic curve would not be a sine-curve as in Euler's theory; as long as the deflections remain small, there is a neutral or astatic equilibrium at a constant critical end load, but Euler's theory must be replaced by one in which the distributed weight is taken into consideration.

Mr. Paaswell refers to the actions of long, medium-long, and short columns as examples of astatic, heterostatic, and orthostatic actions, respectively. These illustrations are well chosen insofar as Euler's theory may be verified experimentally; for example, with hinge-ended steel columns in which the value of $\frac{l}{r}$ is greater than about 150; and insofar as the inevitable eccentric action of the medium length column may be interpreted, according to Articles 24 and 25, as special cases of heterostatic action; and insofar as the short column with $\frac{l}{r}$ less than about 50, does not buckle until the elastic limit has been exceeded.

Mr. Paaswell discusses a two-legged bent supporting a weight, W, at the center of the girder. A buckling of this bent in its own plane would be classified by the writer as a heterostatic action produced by a heterostatic load; for the load may be resolved into orthostatic and astatic components, as follows: The orthostatic component which, acting alone, produces bending stresses in columns and girder proportional to W, consists of the load, W, at the center of the girder and two upward forces, $\frac{W}{2}$, at the ends of the girder, and the astatic component which, acting alone, produces a neutral equilibrium with indefinite deflections of columns and girder at a critical value of W, consists of two downward forces, $\frac{W}{2}$, at the ends of the girder. The combined effects of the two components of the load may be computed by Formula (75) or Formula (102). Unless the columns are slender, the critical values, Q_n, of W are likely to be so large as compared with the actual value, P, of W, that the terms containing the factors, $\frac{P}{Q_n - P}$, may be omitted in Formulas (75) and (102), and the action may be considered as being orthostatic. A buckling of the bent out of its plane under the influence of W would be an example of the mixed astatic action described in Article 23 if the buckling of the bent in its own plane still remains possible; if not, the buckling out of the plane becomes a pure astatic action, and the load, W, at the center of the girder becomes an astatic load.

The case analyzed by Mr. Halmos, of the vertical cylinder supporting a vertical load and resisting an inside pressure, doubtless, is of interest and importance. The vertical load is an astatic load, because at a critical value it

produces an astatic equilibrium with indefinitely increasing deflections. The writer would classify also the internal pressure as an astatic load; for at a critical negative value of this pressure, that is, at a certain outside pressure, pure buckling is produced. The combined vertical load and inside pressure, then, is an astatic load. The case is analogous to that of a simply supported rectangular slab buckling under the influence of a tension in the direction of one pair of sides and a compression in the direction of the other pair of sides; the diagrams in Fig. 7, in Article 10, show that the presence of tension in one direction produces an increase of the value of the critical pressure in the other direction.

Mr. Godfrey mentions the term, "stable neutral equilibrium", which was used by the writer. The term, perhaps, calls for some explanation. A reference to an equilibrium analogous to that of the column will serve this purpose. Consider a spherical ball resting on a horizontal table: The ball is in a neutral or astatic equilibrium because each position into which it may pass by rolling on the table is a position of equilibrium. This neutral equilibrium may be called stable insofar as there is no tendency for the ball to leave the table. Imagine a horizontal edge placed above the table. The ball may be balanced on this edge; and if it is guided by a pair of vertical boards on both sides of the edge, parallel to the edge, and barely touching the ball, the equilibrium obtained, again, is neutral, because it is maintained throughout a continuous range of positions, and it is stable, because the ball will not tend to leave the edge. If the vertical boards are removed, the equilibrium is still neutral, existing throughout the same range of positions, but it is unstable, for the least tilting force would make the ball fall on the table; ultimately, then, the ball would revert to the original state of neutral equilibrium on the table.

Consider a slender hinged-ended column: If the ends are forced to approach each other by a small definite distance, the column will buckle into a sine-curve with one half-wave; at a small change of this distance, the maximum deflection will change, but the elastic curve remains a sine-curve with one half-wave, and the required end load remains the same, equal to Euler's value; the equilibrium is neutral and stable, and is analogous to the equilibrium of the ball on the table. Let the column be simply supported at the center; it will buckle, then, into a sine-curve with two half-waves; the neutral equilibrium obtained is analogous to that of the ball on the edge between the two boards; the reactions at the central support are of the same nature as the reactions of the boards on the ball. If the central support is removed, the column will still be in a neutral equilibrium in the same range of positions; but a small transverse force will disturb this equilibrium, which, therefore, is unstable, like the equilibrium of the ball on the edge when the boards have been removed. If the ends of the column are kept at a constant distance, the elastic curve will revert to the original sine-curve with one half-wave; this reversion to the stable type is analogous to the fall of the ball from the edge to the table. The set of neutral equilibria at the higher astatic loads may be represented in the analogy by a set of horizontal edges, one above the other.

Concerning the matter mentioned by Mr. Godfrey, of the stability of a thin circular cylinder or ring subjected to outside pressure, reference is made

to Part *C* in Mr. Halmos' discussion and to the papers listed in Section *G* in the Bibliography, particularly to Goupil's analysis. In this connection, an article by Hencky,* which appeared recently, may be mentioned; it deals with the stability of a circular ring against warping.

Concerning the coefficients of moments in slabs mentioned by Mr. Godfrey, reference is made to a recent paper on "Moments and Stresses in Slabs", by W. A. Slater, M. Am. Soc. C. E., and the writer.† The coefficient, 0.077, refers not to a slab, but to a double system of crossing-beams, as was discussed at the end of Article 31 (Formulas (158) and (159)).

The writer agrees with Mr. Godfrey concerning the importance of knowing the factor of safety and understanding its significance under the various conditions. As emphasized previously, the ultimate load, and, through it, the factor of safety, are dependent, in the case of medium slender and heavy structures, on the conditions after the proportional limit of the material has been exceeded. Further investigations, following the course indicated by Kármán and Southwell, are needed in this field.

Paper No. 1491

WINTER OVERFLOW FROM ICE GORGING ON SHALLOW STREAMS

By J. C. Stevens,* M. Am. Soc. C. E.

With Discussion by H. B. Muckleston, M. Am. Soc. C. E.

Synopsis

Little has been written on the subject of ice gorging since the report of the St. Lawrence River Commission and the construction of the ice barrier to protect Montreal, Que., Canada. The overflow of certain Western streams, caused by ice gorging during the winter months, presents quite different phases of this question.

The occurrence discussed in this paper is not the overflow caused by ice jams brought about, during the spring break-up, chiefly by blocks of crystalline surface ice being arrested at some constricted part of the river channel and thus forming a temporary dam.

The ice gorge herein discussed occurs during the coldest part of the winter on streams too turbulent to permit the formation of crystalline surface ice; however, frazil and anchor ice are formed in such quantities that the stream becomes a viscous mixture. This results in a rise of the water surface and if the banks of the stream are too low to accommodate this increase of stage, overflow is inevitable.

Increasing the flow of such streams during the winter months by the release of artificially stored water presents an entirely new phase of the problem and merits careful analysis, especially where the overflow may become a menace to life and property.

The facts gathered by the writer during an investigation of the winter overflow from Madison River, Montana, and the effect of storage reservoirs

* Cons. Hydr. Engr. (Stevens and Koon), Portland, Ore.

thereon, are also true of other streams with similar characteristics and uses and should be of more than passing interest in the field of hydraulic engineering.

Statement of the Problem

Madison River rises in Yellowstone National Park and flows in a general northerly direction, uniting with the Jefferson and Gallatin Rivers near Three Forks, Mont., to form the Missouri. It flows through two agricultural valleys locally known as the Upper and Lower Madison Valleys. In these valleys the river banks are low, and near the lower end of each valley the river divides and subdivides into a network of many brush-lined channels.

In these many channeled parts of each valley, during the cold winter months, ice gorges of varying characteristics are formed. These gorges frequently cause the river to leave its channel entirely and flow across the valley floor, occasionally driving the residents from their homes and leaving the valley covered with solidified frazil ice many feet in thickness.

In 1913, the Montana Reservoir and Irrigation Company completed the Hebgen Reservoir. During the summer, this reservoir is operated for the purpose of supplementing the low-water flow of the Madison and Missouri Rivers for the benefit of the Prickly Pear Irrigation Project near Helena, and during the fall and winter for eight hydro-electric plants of the Montana Power Company located on those rivers.

The winter of 1916-17 was one of exceptionally sustained, moderately low temperatures, during which an unusual quantity of frazil and anchor ice was formed. This resulted in ice gorges and extensive overflow of the agricultural lands in both valleys. The question arose as to whether the ice gorging and the overflow were augmented by the operation of the Hebgen Reservoir and of the Madison Reservoir and the power plants in the canyon between the upper and lower valleys (Fig. 1). Accordingly, there was instituted a thorough study of the ice gorging and winter overflow phenomena of Madison River, both from a physical and an historical standpoint, as well as the effect of the operation of the reservoirs and power plants thereon. This was done in order to ascertain whether such operation was responsible wholly or in part for the overflow and to outline, if possible, some remedial measures.

Phenomena of Ice Formation

The temperature of a mixture of ice and water is always at 32° Fahr., as far as practical temperature measurements are concerned. It is a fact that small differences of temperature do exist; the range, however, is a matter of a few thousandths of a degree above or below the freezing point.

This condition is due to the latent heat of fusion of water. Whenever 1 lb. of water passes from the liquid to the solid state about 144 B. t. u. are liberated. Conversely, when 1 lb. of water in the form of ice passes to the liquid state, the same quantity of heat is absorbed in causing the molecular change from a solid to a liquid state and does not appear as a temperature

change in the body. Therefore, a mixture of ice and water maintains a balance of temperature; if it is subjected to a cooling influence, more ice is formed, which liberates just sufficient heat to keep the mixture at a constant temperature, and *vice versa*. It is of interest to note that from every acre of surface ice formed, 1 ft. in thickness, the same quantity of heat is liberated as in the burning of 18 tons of ordinary coal.

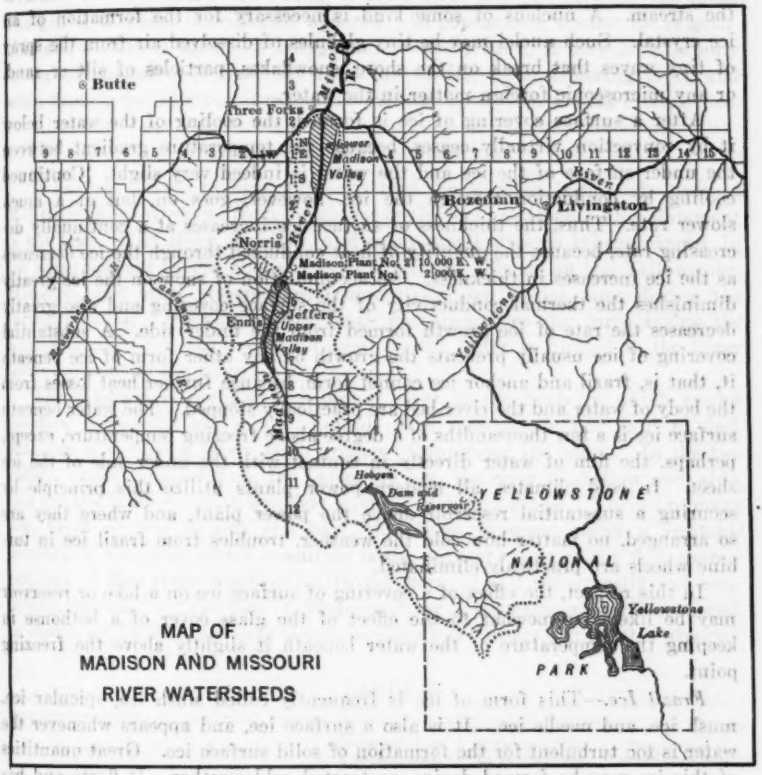

FIG. 1.

There is always a transfer of heat from a warm to a colder body. This transfer takes place by three processes, namely, radiation, convection, and conduction, all of which may be operating at the same time. The water in a river is cooled largely by convection. As the temperature of the air falls below that of the water, a transfer of heat immediately takes place from the warmer water to the colder air. The water at the surface is cooled by contact with the air and becomes denser, therefore, this layer of water sinks and is replaced by warmer water, thus setting up convection currents which gradually cool the whole mass.

When the body of water reaches a temperature of 39° Fahr., a reverse process sets in. At this temperature, water has its maximum density and expands as it is further cooled. Therefore, between 39° and 32° Fahr., the colder water remains at the surface in contact with the cold atmosphere.

Surface Ice.—As soon as the surface layer of water has reached a temperature of 32° Fahr., ice begins to form. From the water's edge the ice crystals begin to spread out over the surface, gradually extending toward the center of the stream. A nucleus of some kind is necessary for the formation of an ice crystal. Such nuclei may be tiny globules of dissolved air from the spray of tiny waves that break on the shore, snowflakes, particles of silt or sand, or any microscopic foreign matter in the water.

After a surface covering of ice is formed, the cooling of the water below it by convection virtually ceases, because the temperature gradient between the under surface of the ice and the water is indeed very slight. Continued cooling by conduction through the ice, however, goes on, but at a much slower rate. Thus, the thickness of surface ice increases at a continually decreasing rate, because the quantity of heat conducted through the ice decreases as the ice increases in thickness. An accumulation of snow on the ice greatly diminishes the thermal conductivity of the surface covering and also greatly decreases the rate of ice growth formed from the under side. A substantial covering of ice usually prevents the growth of any other form of ice beneath it, that is, frazil and anchor ice cannot form, because further heat losses from the body of water and the river bed are practically stopped. The water beneath surface ice is a few thousandths of a degree above freezing temperature, except, perhaps, the film of water directly in contact with the under side of the ice sheet. In cold climates, all modern power plants utilize this principle by securing a substantial reservoir above the power plant, and where they are so arranged, no matter how cold the weather, troubles from frazil ice in turbine wheels are practicaly eliminated.

In this respect, the effect of a covering of surface ice on a lake or reservoir may be likened somewhat to the effect of the glass cover of a hothouse in keeping the temperature of the water beneath it slightly above the freezing point.

Frazil Ice.—This form of ice is frequently called slush ice, spicular ice, mush ice, and needle ice. It is also a surface ice, and appears whenever the water is too turbulent for the formation of solid surface ice. Great quantities of this ice may be formed during protracted cold weather. It floats and has the general appearance of snow in the water, but on examination is found to consist of small spicules or needle-like crystals which have a tendency to cohere in masses. The entire water area of the river may become impregnated with frazil ice, forming a mixture much more viscous than water, which causes a retardation of velocity with a consequent increase of stage. Favorable conditions for its formation are turbulent water with cold, strong, up-stream winds and cloudy weather.

Anchor Ice.—Except at its place of formation, which is on the bed of clear shallow streams, anchor ice can hardly be distinguished from frazil ice. The cause of its formation is the rapid radiation of earth heat from the river bed

into space. It forms most rapidly on dark-colored stones, during clear cold nights, and it will not form under bridges, in the shade of overhanging trees, during cloudy weather, and seldom or never under surface ice or in water which is heavily loaded with frazil ice or silt. It is purely a product of radiation and, in this respect, forms under the same conditions as hoar frost.

With a slight rise of temperature during clear, sunny days, this anchor ice will rise to the surface. In rising, it often lifts and carries away the rocks and gravel to which it originally adhered. In appearance, anchor ice is granular and somewhat resembles honeycomb. Once formed, it may grow rapidly by an accumulation of frazil ice from the flowing water adhering to it, and when floating in the river, it cannot be distinguished from a mass of frazil ice.

Causes of Winter Overflow

It has been stated by local authority that the Madison is the only river in Montana which overflows from ice gorges during cold weather. This statement is not true. The Ruby, Boulder, and many small streams behave exactly in the same manner as the Madison in this respect. Floods on the Yellowstone, Missouri, and other streams are frequently caused by ice jams during the spring break-up. Ice gorges from frazil and anchor ice also form during the winter months, but the overflow caused by the latter is limited to the lower lands adjacent to the river.

The Madison is probably the largest river in the State in which winter overflow conditions are so pronounced. The reasons are not hard to find. Madison River has a fairly steep gradient throughout its course. In the two valleys under consideration, the banks are low, the river is shallow and wide, and the bed is strewn with boulders, cobblestones, and gravel. There are many low, brush-covered islands and bars, that form in some places a veritable network of channels, which condition is the natural result of the flow characteristics of this river, combined with the slope of and the gravelly soil composing the valleys. The flow of Madison River is comparatively uniform, and, as shown by Table 1, has only about one-fourth the range of the other streams

TABLE 1.

Stream.	Locality.	Maximum flow, in second-feet.	Minimum flow, in second-feet.	Percentage of maximum flow.
Yellowstone	Huntley	47 900	1 060	2.2
Jefferson	Silverstar	16 500	320	1.9
Gallatin	Logan	5 400	178	3.3
Madison	Plant No. 2	9 500	1 200	12.6

Other things being equal, a stream with extremes of flow will have a deeper channel in its self-made valleys than one with a low range of flow. Therefore, the Madison, with its low range of flow, has banks averaging about 5 ft. in height through the valleys.

The water surface of a stream carrying large quantities of frazil and anchor ice is raised by reason of the reduction in velocity caused by the increased

viscosity of the flowing mixture. A condition is soon reached in which the river changes from a turbulent to a placid stream. If the banks are high enough, this placid condition is reached before overflow occurs and surface ice is formed, which effectually prevents the further formation of frazil and anchor ice beneath it. Unfortunately, the banks of the Madison River are so low that overflow often occurs before this condition is reached and is the principal reason for the extensive winter overflow from ice gorges.

The immediate cause of overflow is the formation of ice gorges induced by low temperatures, and such gorges invariably occur during a protracted period of cold weather. When the river water is cooled to the freezing point, frazil ice immediately begins to run. If the nights are cold and clear, anchor ice will form, and if the days are clear, these masses rise and float away. If the days and nights are cloudy, anchor ice does not form, but a greater quantity of frazil ice is created. During storms, snowflakes and frozen spray falling into the water form nuclei that aid in the growth of frazil ice. Thus, whether the atmosphere is clear, cloudy, or stormy, if the air temperatures are lower than freezing, the river, once the water has been cooled to the freezing point, is continually manufacturing ice, the rate depending on the air temperatures below 32° Fahr.

In the Upper Madison Valley, the ice gorges usually begin just above the upper end of the Madison Reservoir. This part of the valley is broken into a network of channels, and there are a great many low brush-covered islands and bars and innumerable obstructions to flow. In the Lower Madison Valley similar conditions exist.

With the accumulation of frazil and floating anchor ice, these channels become completely choked and the river is virtually dammed with ice. Overflow is inevitable. First, the low sloughs and overflow channels are filled with water on which may form surface ice, and over which the river flows with its load of frazil. These channels soon are filled as high as the surrounding land, which causes the river to seek new outlets. In this manner the overflow spreads, and the water frequently leaves its natural bed altogether and flows over the surrounding bottom-lands. A water channel tends to choke itself with frazil ice; thus, the water is continually changing its path of travel and virtually raises the entire bottom to an irregular level of ice. While the cold continues, this frazil, exposed to the air, solidifies in huge masses, forming effective banks. There is practically no limit to the extent of overflow or ice accumulation that may occur as long as the critical degree of cold continues.

The surface ice at the edges is broken off by the rising water and floats down to add its volume to the gorge. These cakes frequently lodge edgewise and form an effective barrier for the accumulation of frazil and anchor ice. With a few days of rising temperature, the river begins to cut through and flows under the ice in its original channel, gradually clearing it of the accumulated ice. Oftentimes, banks of frazil 7 or 8 ft. high are left along the river's edges.

Two types of ice gorges were recognized on Madison River, namely, that designated as the "bridging gorge", in which little or no overflow occurs, and that called the "overflow gorge".

FIG. 2.—TYPICAL GORGE OF THE "BRIDGING" TYPE.

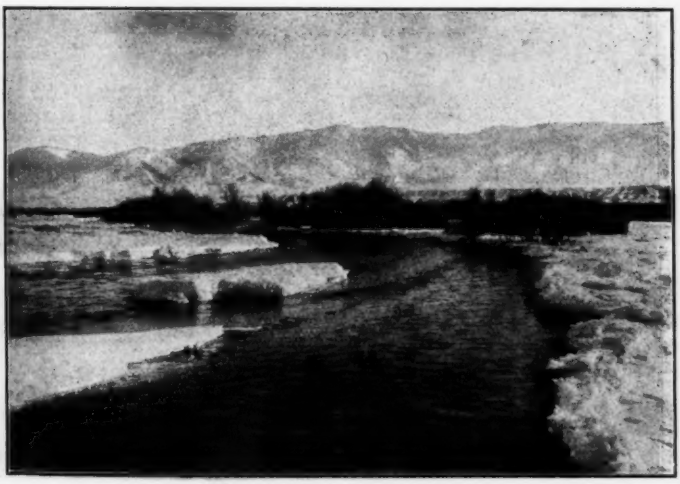

FIG. 3.—APPEARANCE OF RIVER AFTER ICE GORGE HAS BROKEN AND THE WATER HAS RETURNED TO ITS CHANNEL.

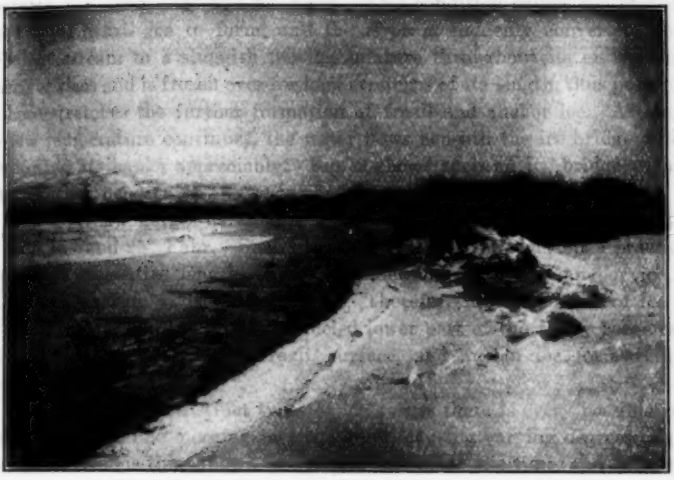

FIG. 4.—FRAZIL ICE FLOATING IN RIVER CHANNEL.

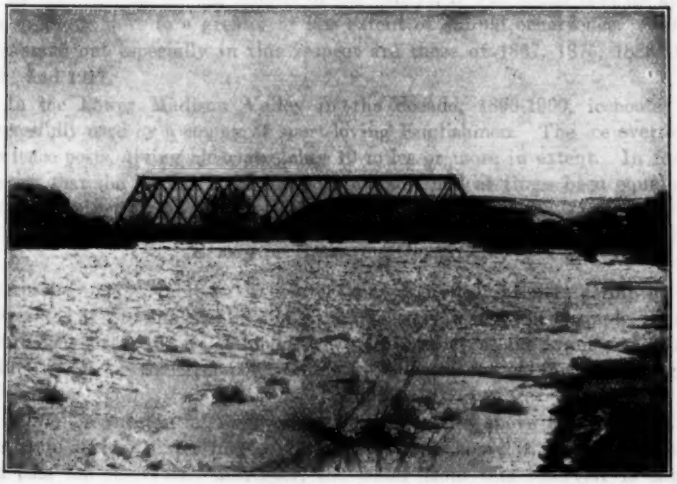

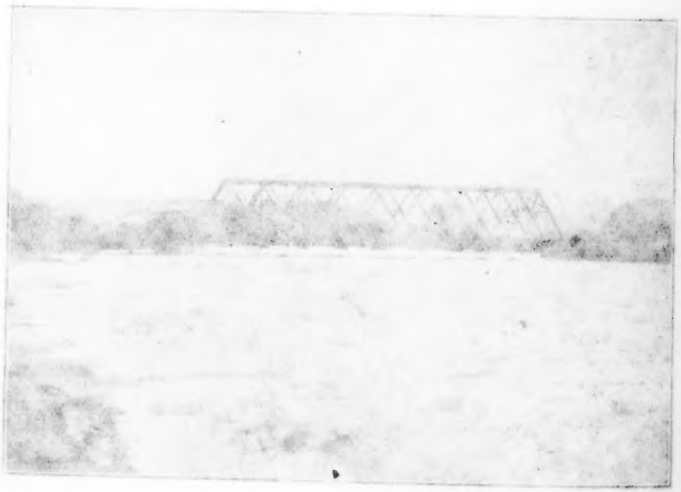

FIG. 5.—ICE GORGE OF THE "BRIDGING" TYPE ON GALLATIN RIVER.

The "bridging gorge" is caused by sudden and sustained extreme low temperatures, say, from −15° to −30° Fahr. This condition causes the maximum quantity of frazil ice to form, and the river is suddenly converted from a turbulent stream to a sluggish flowing mixture throughout its entire length. The river rises and is frozen over for long stretches of its length, thus preventing in these stretches the further formation of frazil and anchor ice. As long as the low temperature continues, the water flows beneath the ice bridge without overflowing its banks appreciably. Fig. 2 shows such an ice bridge with the water flowing beneath it.

The "overflow gorge" is caused by sustained moderate temperatures, say, between 15° and 25° Fahr. Such a condition leaves the river open practically throughout its entire length, causes considerable frazil and anchor ice, but not enough to form a "bridging gorge". Therefore, the formation of ice continues unabated, and the many channeled lower part of the valley becomes the gathering ground for all the frazil, surface, and anchor ice formed in the river above.

Between these two distinct types of ice gorges there is every possible intermediate type, the one merging into the other, causing varying degrees of overflow. The river is thus known to overflow one place one time, and some other place another time, in fact, every possibility of gorging and overflow between the two extremes is known to have occurred. So capricious are these overflows that, during the winter, stock is never allowed to pasture in the bottomlands. In the history of these valleys, thousands of head of cattle have been trapped and lost in the winter overflow.

By interviewing the old settlers of the valleys, it was found that ice gorges and overflows were to a greater or less extent of annual occurrence. Winters that stand out especially in this respect are those of 1867, 1875, 1883, 1898, 1910, and 1917.

In the Lower Madison Valley in the decade, 1890-1900, iceboats were successfully used by a colony of sport-loving Englishmen. The ice overtopped the fence posts, giving clear stretches 10 miles or more in extent. In fact, it appears that the limits of the 1916-17 overflow had at times been equalled if not exceeded.

Effect of Reservoir Operation

Apart from an increase in winter flow, the effect of a reservoir in such a stream is first to diminish the quantity of ice below it. For example, consider a turbulent river, 100 miles in length, with a valley at the lower end. In its natural condition the river pours into this valley all the ice formed throughout its length.

Now, if a substantial reservoir is built 25 miles above the valley, it will constitute an ice barrier for the 75 miles of river above it, since no frazil ice can pass the reservoir. Moreover, the water from this reservoir is slightly above freezing temperature and frazil ice cannot form until the water has been cooled to freezing in the channel below. It is obvious, therefore, that after the construction of the reservoir the quantity of ice reaching the valley

will be limited to that formed in the lower 15 or 20 miles of river, whereas, prior thereto, 100 miles of river contributed its ice to the valley.

The first effect of increasing the flow is to diminish the quantity of anchor ice that may form, due to the increased depth of water reducing the quantity of heat that may be radiated directly from the bed of the stream.

The second effect is to diminish the turbulency and encourage the tendency of the water, at freezing temperature, to remain on the surface. Thus, the formation of frazil ice is more likely to be confined to the surface of the moving water, which is not the case when the water is brought to a uniform freezing temperature by thorough mixing.

The third effect is to increase the quantity of frazil ice about in proportion to the increase in the area of the water surface.

The fourth effect is to increase greatly the transporting power of the current, thus enabling the river better to carry its icy load without gorging and, therefore, delay the formation of the gorge until a rise of temperature destroys the tendency of the ice to gorge. The increased flow tends to cut out the gorge quicker with a slight rise in temperature; in other words, the river becomes more sensitive to the temperature changes and the duration of the overflow is less than with the normal flow. For example, consider a typical cross-section of Madison River, as given in Table 2.

TABLE 2.

Gauge, in feet.	Mean depth, in feet.	Width, in feet.	Discharge, in second-feet.	Area, in square feet.	Mean velocity, in feet per second.	Transporting power.
2.0	1.84	177	880	325	2.60	1
2.5	2.19	186	1 470	425	3.45	6
3.0	2.80	195	2 350	545	4.31	21
			Increase in Percentage:			
2.0 to 2.5	19	5	67	31	33	500
2.0 to 3.0	52	10	167	68	66	2 000

It is stated in textbooks on hydraulics that the weight of bodies which can be moved by a current varies as the sixth power of the velocity, hence the increase in transporting power, corresponding to an increase of 67% in discharge, is 500%, and an increase of 167% in the discharge increased the transporting power 2 000 per cent. Of course, when the river becomes loaded with frazil ice, the velocity is somewhat reduced and the river rises, the flow remaining constant. With the increased flow and a loaded river, the full effect of the increase in transporting power is not felt, but, nevertheless, there is a decided increase in its transporting power and its ability to prevent and to cut out gorges. If the quantity formed varies as the surface exposed, there is only a 10% increase of frazil ice with 167% increase of discharge.

The change in the winter régime of a river by reason of the operation of reservoirs, results from five causes. The effect of four of these causes is to diminish the quantity of ice formed, and only one has the effect of increasing it; hence, the net effect of the construction and operation of reservoirs on the

Madison River was to diminish the quantity of ice and ice gorging. As applied to Madison River, this fact was abundantly verified by the testimony of old settlers still living in the valleys.

The next point of inquiry is whether a reduction in the quantity of ice might not increase the overflow in some manner by making the general type of gorge conform more nearly to that of the "overflow gorge" in distinction to the "bridging gorge", as previously defined. This question is intimately associated with temperatures and windy, clear, or cloudy days and nights. For any given set of climatic conditions, it is acknowledged that the effect of reservoir operation on the Madison River has been to reduce the total quantity of ice, to delay the formation of gorges, and to hasten the return to normal conditions. This effect results from physical causes which, if valid for one part of the valley, must be valid for all parts. What then produced the abnormal overflow in the Madison Valleys in 1916-17? The answer is readily found in abnormal climatic conditions.

The deduced mean natural flow of the Madison River at Plant No. 2, situated between the Upper and Lower Valleys (Fig. 1), during the months, November to March, each winter, and the increases in flow resulting from the operation of the Hebgen Reservoir, are given in Table 3.

TABLE 3.

Winter season, November-March.	Deduced mean natural flow, in second-feet.	Additional flow from Hebgen Reservoir, in feet.	Percentage of increase.
1914-15	1 600	440	28
1915-16	1 540	530	34

The Hebgen Dam is about 60 miles below the source of the river and by creating a reservoir about 20 miles in length, has the effect of eliminating approximately 100 miles of river which before the construction of the dam contributed large quantities of ice to the lower valleys. Ice gorges now form above the reservoir as in previous years, but this mobile ice is melted in its passage under the surface ice of Hebgen Reservoir. The water issuing from the dam is free from ice and its temperature is slightly above the freezing point; therefore, no ice can form in this river until the water has again been cooled to the freezing point. It has been found by observation that no appreciable quantity of frazil ice, even in extreme temperatures, begins to form within 10 miles below the dam.

The effect of the Hebgen Reservoir, therefore, aside from the question of increased flow, has been to diminish the quantity of ice reaching the Upper Madison Valley. For the same reasons, the Madison Reservoir which is at the head of the canyon between the two valleys (Fig. 1), has the effect of still further diminishing the quantity of ice in the Lower Valley by eliminating

about 80 miles additional of ice-producing river channel. Hence, before the construction of either reservoir, the Lower Valley was the gathering ground for the ice produced in 150 miles of river. By the construction of the reservoir, the length of ice-producing channel has been reduced to about 25 miles.

During the winter of 1916-17, as a result of the operation of the Hebgen Reservoir, the mean increase in flow was 65%, and, during certain periods, it was more than doubled. Yet the increased quantity, if no ice was present, is only about one-fourth the capacity of the river channel before overflow occurs.

Ice-Forming Factor

The real cause of the unusual overflow of 1916-17 in the Madison Valley was abnormally sustained moderately low temperatures. The rapidity with which ice will form is dependent far more on the drop in temperature below freezing than any other factor, provided that drop is not sufficient to form a "bridging gorge" throughout the length of the river and thus prevent the further formation of ice. Clear days and nights, cloudy weather, winds, and snows, all have their effect, but they are of minor importance in comparison with the temperature gradient.

The quantity of ice formed will depend on the amount of heat lost from the water. The heat lost after water has been cooled to 32° Fahr. and ice has begun to form is the latent heat of fusion. Virtually, 1 lb. of water is frozen for every 144 B. t. u. extracted from the water. Practically, the same amount of heat is lost in 1 day with a drop in temperature of 10° as is lost in 2 days with a drop of 5°; hence, the number of degree-days below freezing in any period will be the measure of the quantity of ice formed during that period.

When the air temperature is above the freezing point, heat passes from the air to the water, and latent heat is absorbed by the water with a reduction in the proportion of ice. The quantity of ice thus lost is also measurable by the degree-days above freezing. Hence, in any period, the net quantity of ice is measured by the excess of degree-days below freezing over those above that temperature. These relations, of course, only hold as long as the river remains open and a mixture of ice and water may be considered.

Fortunately, long-time records of temperature were available at Bozeman (and Fort Ellis), Mont. These records beginning in 1868 were practically continuous to date. A comparison of temperature records at Bozeman with those obtained in recent years at Madison Plant No. 2, at Ennis, and at Three Forks, shows that the Bozeman records represent very accurately the temperatures in both the Upper and Lower Madison Valleys, and may be safely used to fix relative yearly variations.

The mean daily temperatures for the months of November to March, inclusive, for each winter, were plotted. The winter season was considered to begin on the first date in the fall that the mean daily temperature fell below freezing and to end with the date it rose above freezing in the spring. The areas of these temperature curves below freezing in excess of those above freezing were found by means of a planimeter. These areas gave for each winter season the number of degree-days below freezing in excess of those

above freezing. This quantity was called the ice-forming factor for that season. Figs. 6 and 7 show the temperature curves for the winters of 1871-72 and 1916-17, respectively. Fig. 8 shows the ice-forming factors for each of the 53 years of record, arranged in chronological order, and Fig. 9, the same factors arranged in order of magnitude. With the exception of the winter of 1871-72, it is seen that the winter of 1916-17 shows the greatest ice-forming factor during the entire 53 years.

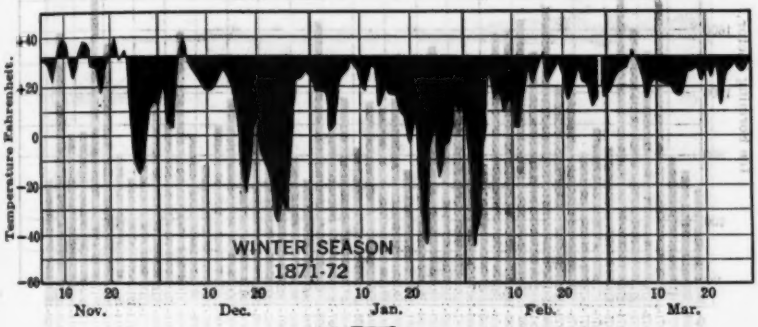

FIG. 6.

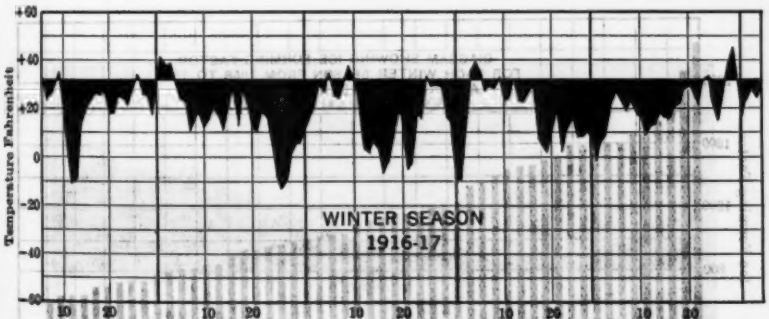

FIG. 7.

The ice-forming factor alone is no measure of the overflow, but merely indicates the net quantity of ice-forming influence from temperatures that obtained during the winter. Overflow results from the type of gorge produced, and one must look to the daily temperature curves themselves in order to judge of the nature of the gorges that would be formed. A comparison between Figs. 6 and 7 shows at a glance why the gorge produced during the winter of 1916-17 was of the overflow type, while that of 1871-72 was more likely to have been a "bridging gorge" which did not produce any unusual overflow.

From this analysis the conclusion was inevitable that the year showing the greatest ice-forming factor and, at the same time, in which the highest temperatures obtained, was the one producing maximum overflow. Of all the years of record, the winter of 1916-17 was the most abnormal in this regard.

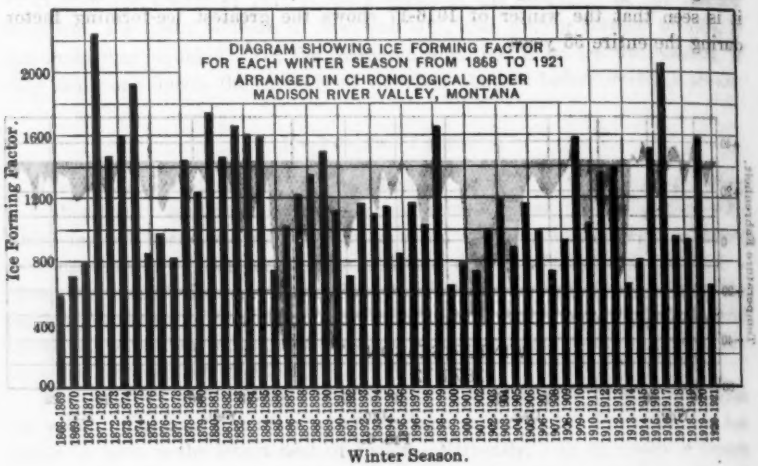

FIG. 8.

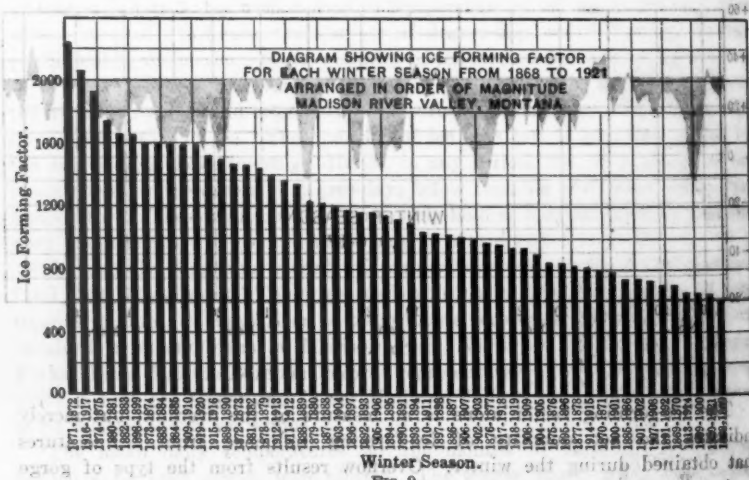

FIG. 9.

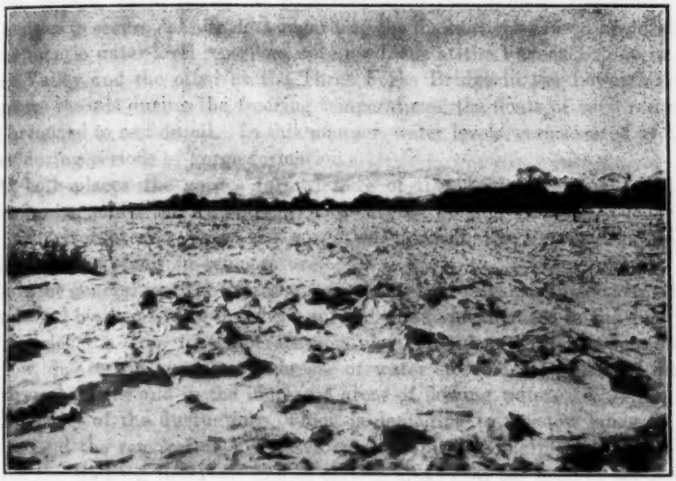
FLUCTUATIONS CAUSED BY ICE GORGING

Obviously, when an ice gorge has formed and overflow has commenced, great fluctuations in flow and in river stage are produced. During the formation of the gorge, a great quantity of water is converted into ice and remains in



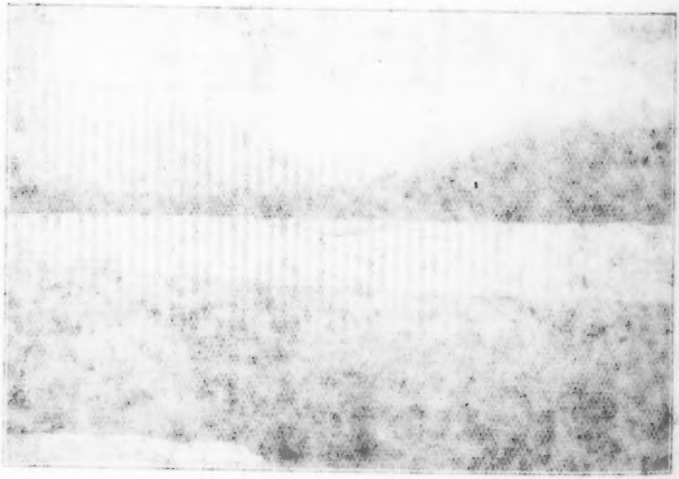


FIG. 10.—FRAZIL ICE LEFT ON AGRICULTURAL LANDS AFTER RIVER HAS RETURNED TO ITS CHANNEL.

FIG. 11.—BROKEN ICE LINE ON BANK SHOWS HEIGHT TO WHICH WATER WAS RAISED AT TIME OF FORMING OF GORGE.

temporary storage until released by a rise in temperature. In fact, it was the inability to secure water for power-plant operation in the canyon between the two valleys, which led to the construction of the Madison Reservoir.

In order to secure definite data regarding the fluctuations caused by gorging, two automatic water-level recorders were used, one at the Varney Bridge in the Upper Valley and the other at the Three Forks Bridge in the Lower Valley. To insure records during the freezing temperatures, the floats of each recorder were arranged to rest on oil. In this manner, water levels were secured at both places during periods of gorge formation.

At both places, the gorges formed were of the "bridging" type, with the water flowing under the ice and carrying varying quantities of frazil ice from the open river above. Once the gorge was formed, the fluctuations follow broadly the variations in temperature.

It is the general tendency for water to rise with a fall in temperature. This is explained by the slowing up of the current due to an increase in the quantity of frazil ice. A drop in temperature is also coincident with a reduction in the flow, due to the temporary increase of water stored in the form of ice in the river channels, and in the increased areas of flowing water.

One effect of the fluctuations, which is damaging to meadow lands, is the cutting and the removal of sod. Evidence of this was plainly seen near the head of the Madison Reservoir and in certain areas near the head of the gorges in the Lower Valley. In some of the meadows and pastures, the sod had been badly cut by the ice. Examined early in June, 1917, the peculiar phenomena were seen of irregular patches of sod from 1 sq. yd. to 50 sq. yd. in area resting on top of several feet of ice, the explanation of which is simple.

The first overflow covered the land with a sheet of water, which, in freezing, became attached to the sod. A second flooding covered this ice 1 ft. or more in depth. The ice on the bottom was cracked and broken in irregular patches and rose to the surface carrying with it the sod on which it was first formed. Later, as the gorge increased, the depth of water became greater and the current flowing under the surface ice, being impregnated with frazil ice, soon filled completely the space between the surface ice and the ground. The ice under the sod is protected and is the last to disappear when the ice melts in the spring. Hence, these patches resembled huge toadstools of ice with sod caps.

Some of these ice cakes with sod adhering to them float away and in melting deposit the sod in adjacent fields. Generally, however, by becoming a part of the surface ice in the ponded water immediately above the ice gorge, they are held in place and, in melting, deposit the sod near the place from which it came, except that it is usually moved a few inches down stream or tilted and broken.

There are evidences throughout both valleys that this process is a natural phenomena of overflow from ice gorges and has been going on from time immemorial.

Remedial Measures

It was previously pointed out that the banks of the Madison River are not sufficiently high to retain the water in its channel while the stage increases as

a result of retarded velocities due to its ice load. Overflow often occurs before the surface can bridge over with ice and thus prevent the further formation of frazil and anchor ice.

The obvious remedy is to increase the height of the banks by dikes. In the Lower Valley, as a result of this investigation, a diking district was organized by the land-owners affected and a dike 11 miles in length was built. The top of the dike was constructed 10 ft. above low water, and the dike was placed as near the river bank as possible consistent with protection from under-cutting. Where necessary, ordinary culverts without trap-gates were built through the dike for drainage. The effect of this will be to prevent future overflow, but it will be necessary to irrigate some of the lands which previously were watered from these overflows. Undoubtedly, the winter overflow was a benefit in the raising of wild hay crops, and whether or not all overflow should be prevented can only be determined on the merits of each tract or area as governed by its local conditions.

DISCUSSION

H. B. MUCKLESTON,* M. AM. SOC. C. E. (by letter).—The phenomena exhibited in ice and ice formation are of great material interest to hydraulic engineers and especially where their work is in altitudes or latitudes sufficiently high to make trouble from ice formation a matter of annual occurrence. In spite of the valuable research work already done, there is room for a great deal more, and contributions to the knowledge of the subject are a welcome addition to science.

The *modus operandi*, causes, and effects of ice formations are still obscure in many phases, notwithstanding its apparent simplicity. The formation of the so-called frazil ice is one subject on which the last word has not been said. It is possible to cool water to a temperature much below its freezing point, provided the water is absolutely still, for example, in a glass jar. Sudden agitation by shaking or even inverting the jar will cause it instantly to congeal. A similar action may be noted sometimes when large quantities of frazil ice float in practically still water without solidifying. Very slight agitation, such as that caused by the sudden opening of a submerged valve may result in the instantaneous freezing of the whole into a solid mass.

Anchor ice forms on the bed of shallow streams; but shallowness is a relative term, since anchor ice has been observed under 10 ft. of water. A similar formation sometimes occurs in flumes, particularly in those constructed of metal or concrete, and in metal pipes entirely exposed to the atmosphere. Where the pipes rest on earth, it has also been noticed that anchor ice forms only on the part exposed to the air. It will form under bridges if conditions are right.

The size of stones which at times are lifted by anchor ice, is astonishing; one weighing 52 lb. has come under the writer's observation. It might also be noted that these stones may get into all sorts of unexpected places; in one case, a pear-shaped boulder became lodged in the groove of a Stoney gate, and had to be broken before it could be removed.

The statement that the transporting power of water varies as the sixth power of the velocity needs qualification. First, it refers to bodies of higher specific gravity than water; second, it refers to movement of any kind, not merely floating or apparent floating, such as may occur with suitably shaped objects in violent streams; as, for example, the locomotive which serious witnesses were prepared to swear floated on the Johnstown flood. In so far as ice, or other light material is concerned, the transporting power depends on the depth. The eroding power of water in motion is another matter.

A phenomenon which is observed in rivers in the "chinook belt" east of the mountains, is known as over-flooding. The less turbulent streams usually freeze over more or less completely, early in the winter. As the result of a continued cold snap, the discharge is somewhat reduced and, as a consequence, the ice in mid-stream sags perhaps several inches or even feet. A chinook increases the discharge rapidly to a quantity which the channel under the ice cannot accommodate, and, as a result, the water flows in a thin sheet over the

* Chf. Engr., Lethbridge Northern Irrig. Dist., Lethbridge, Alberta, Canada.

ice and freezes. This results in extremely thick ice, especially on the edges, which is prone to remain solid long after the ice in the center is rotten. When it finally does float away, it is in excellent shape to cause jams in the first suitable place. In one case, on a stream much used for skating, this phenomenon was a regular afternoon occurrence on warm days. Skaters going up the river would meet a thin sheet of water about an inch or less in depth flowing down. This water was always frozen the next morning; but if the air was warm enough, that is, just above freezing temperature, it would always recur about three or four o'clock in the afternoon.

Paper No. 1493

THE AREA OF WATER SURFACE AS A CONTROLLING FACTOR IN THE CONDITION OF POLLUTED HARBOR WATERS

By Richard H. Gould,* Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. W. C. Purdy, Allen Hazen, Warren R. Borst, Kenneth Allen, H. W. Streeter, George A. Soper, H. W. Clark, Gordon M. Fair, and Richard H. Gould.

Synopsis

The sources of oxygen required to meet the demand of the polluting matter in the waters of New York Harbor are discussed in this paper. It is shown that the air is the most important source of this oxygen which is obtained by direct absorption through the water surface. The conclusion is, that under aerobic conditions, oxygen dissolved in the harbor waters will be depleted by the demand of the polluting matter until a condition is reached where oxygen is absorbed from the air at the same rate at which it is abstracted by the fermenting material in the waters.

During 1920, the writer had occasion to make a number of tests and observations on the pollution of the waters of parts of New York Harbor and some of its tributaries. As a result of this work, and of other studies, he has been impressed by the tremendous part apparently played by atmospheric oxygen in supplying the oxygen demand of the polluted harbor waters and in preventing obnoxious conditions. The importance of atmospheric oxygen in this connection has been stressed by other writers, notably by Dr. W. E. Adeney in his report to the New York Metropolitan Sewerage Commission, published in 1912. Others, however, have credited this factor with little influence on harbor conditions. In advancing opinions in support of the former view, the writer recognizes that the basic data available for study are meager, and this paper is presented with the purpose of developing additional information.

* Prin. Asst. Engr. with James H. Fuertes, New York City.

The data under discussion were secured by the writer in a series of dissolved oxygen analyses, covering a period from July to December, 1920, made in connection with a report by James H. Fuertes, M. Am. Soc. C. E., to the municipal

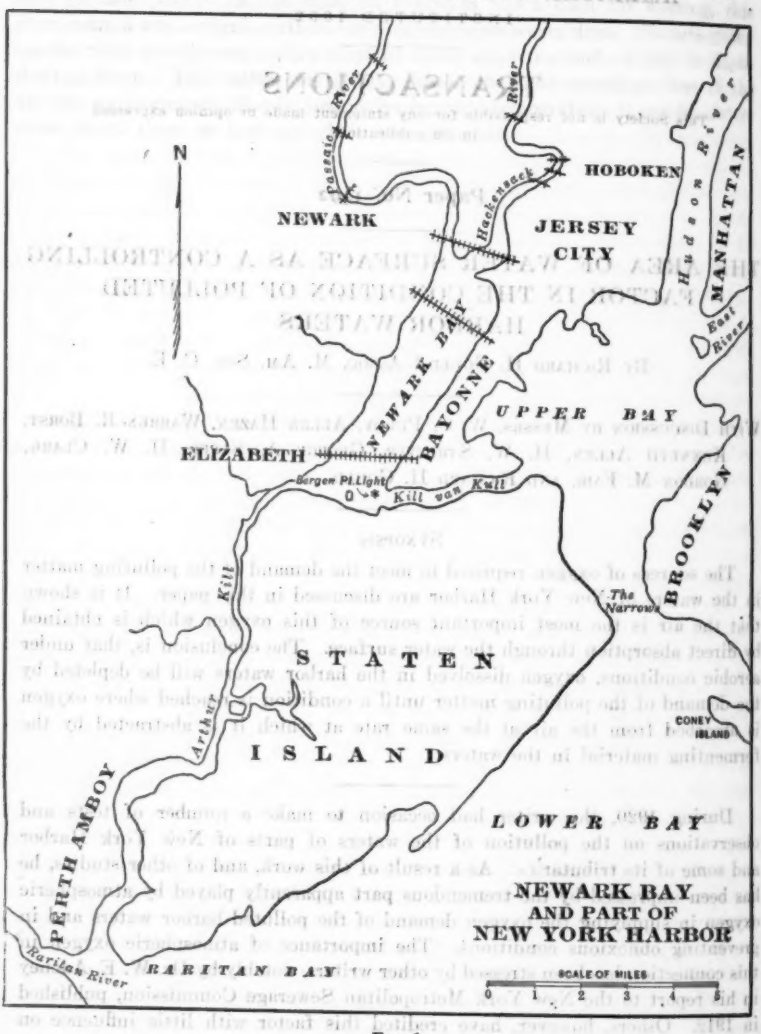

FIG. 1.

authorities of Elizabeth, N. J. These data were taken principally on the Jersey side of New York Harbor, mostly in Newark Bay, Kill van Kull, Arthur Kill, Raritan Bay and tributary streams (Fig. 1). The analyses were carried out

in accordance with methods used by the Metropolitan Sewerage Commission, and the large amount of data given in the valuable reports of this Commission have been used freely to supplement the new data which necessarily were limited.

In the course of the investigations, it was observed that, at times, the dissolved oxygen content of the water changed rapidly from day to day and that the changes seemed to be due primarily to the wind, that is, following a brisk wind which caused considerable wave disturbance, the dissolved oxygen content of the waters might be much higher than is usual in calm weather under similar conditions of temperature and dilution with sea water. For example, on August 24th, 1920, the dissolved oxygen in Newark Bay, at the Lehigh Valley Railroad Bridge, was 14% of saturation, and eight days later, at this point, it was found to be 75% of saturation. In the first case, there was little wind and wave disturbance, whereas in the latter there was much wave motion caused by a brisk northwest wind. At another time, in the Arthur Kill, at Elizabeth, N. J., the dissolved oxygen value increased from 19% at 9:25 A. M., to 52% at 4:00 P. M. of the same day. No doubt, these are extreme cases, but they indicate the importance of the wind and possibly other natural phenomena on the dissolved oxygen content of the harbor waters.

The fluctuation of dissolved oxygen values, in the Arthur Kill, at Elizabeth, is shown graphically on Fig. 2 for certain days in the period from July to December, 1920. The percentage of sea water present and the temperature of the water are also shown on the diagram. Average daily wind velocities, as obtained by the Weather Bureau on the roof of the Whitehall Building in Lower Manhattan, are also shown. This station is about 6 miles from Newark Bay and at considerable elevation, hence the velocities obtained do not represent actual wind velocities at the surface of Newark Bay. They do show, however, the relative fluctuation in the wind currents, and are valuable, at least, to that extent.

It may be noted that the majority of high saturation values follow or are concurrent with relatively high wind velocities, and, conversely, that the lower saturation values follow lower wind velocities. A quantitative relation between wind velocities and dissolved oxygen content is not apparent from present data, but such a relation could be obtained, no doubt, if sufficient data were available on wind velocities and their direction and on dissolved oxygen content. Although this information would be interesting and of some value, engineers are concerned to a greater extent in the quiescent condition of the harbor waters. The critical conditions for fish life and for the production of nuisances occur when the dissolved oxygen is depleted to the greatest extent.

The chief interest in the effect of wind velocity on the dissolved oxygen content, as far as this paper is concerned, is the attention it draws to the importance of atmospheric oxygen in the maintenance of dissolved oxygen values in the waters. It seems probable that the chief effect of the wind is to ruffle the water surface and, therefore, increase the area exposed to the air. That such decided changes in the dissolved oxygen content occur when the area of the water surface is thus increased, leads to the opinion that oxygen absorbed from the air even through the quiescent water surface may be of considerable

importance. An effort was made, therefore, to define the relative importance of the sources of oxygen to the polluted waters by a study of conditions in Newark Bay.

Newark Bay is a shallow basin, with an average depth of about 6.9 ft. at low tide and a water surface area of about 8.06 sq. miles. Its location in reference to New York Harbor is shown on Fig. 1. The Hackensack and Passaic Rivers flow into Newark Bay at its upper or northern end, and their outlet to the ocean is through two channels, namely, the Kill van Kull, connecting Newark Bay with Upper New York Bay, and the long reach of the Arthur Kill, connecting Newark Bay with Raritan and Lower New York Bays. The waters in the tidal prisms of Newark Bay and of the Passaic and Hackensack Rivers flow back and forth through the two "Kills". According to the U. S. Coast and Geodetic Survey, 84% of these waters pass through Kill van Kull and 16% through Arthur Kill.

The waters of Newark Bay are heavily polluted. The inflowing Passaic River has been in a septic condition for years, as it receives the untreated sewage from Paterson, Passaic, Newark, and smaller communities. The Hackensack River is polluted to a lesser degree; however, it carries considerable waste material, and all the bordering cities, Jersey City, Bayonne, Elizabeth, and Newark, as well as the Borough of Richmond, New York City, discharge a part of their untreated sewage into the waters of Newark Bay. The waters of Upper New York Bay are polluted by sewers draining into New York Harbor, and tidal currents force a part of these waters into and out of Newark Bay.

An estimate was made of the quantity of this waste material entering the Bay and also its probable oxygen demand for the period of its retention in the Bay waters. The visible sources of oxygen to meet this demand were then measured and estimated to determine the relative importance of the various oxygen sources in preventing obnoxious conditions in the Bay.

The volume of the polluting material can be estimated approximately from the population whose wastes flow into the waters. For purposes of the computation, all the sewage flowing into the tidal waters of the Passaic and Hackensack Rivers and Newark Bay was included. The City of Elizabeth lies at the junction of Newark Bay and Arthur Kill, its sewage being carried north into Newark Bay on the flood tides and south into Arthur Kill on the ebb tides. For present purposes, one-half the volume of its sewage and that from a joint municipal sewer discharging at Elizabeth are considered as being tributary to Newark Bay.

The determination of the oxygen demand of the sewage which finds its way into the Bay is more complicated. This demand is dependent on the strength of the sewage, on the length of time it is in contact with the waters of the Bay, on the temperature, and on the nature of the bacterial actions taking place.

In a report to the Metropolitan Sewerage Commission published in 1912, Adeney estimates that the total oxygen requirement of settled New York sewage, at 0° cent., and 760 mm. barometer, would be not more than 250 cu. cm. per liter, and that about 60% of this amount would probably represent

FIG. 2.

the demand during 48 hours under actual harbor conditions in summer, with a temperature of 25° cent. This latter figure corresponds to about 570 cu. cm. of oxygen per gallon of sewage.

The Metropolitan Sewerage Commission has made a number of small-scale experiments on the oxygen demand of New York sewage, with different dilutions of sewage and fresh water, the results of which varied considerably with the dilution used. From its work, however, the Commission estimated that about 1 428 lb. of oxygen would be required to oxidize 1 000 000 gal. of raw sewage. This is about 80% of that estimated by Adeney for the demand of settled sewage in New York Harbor. The estimate of the Metropolitan Sewerage Commission corresponds to about 455 cu. cm. of oxygen per gallon of sewage.

It is well to bear in mind the great difficulty in reproducing harbor conditions in small incubation samples. The dilution of sewage with harbor waters is uncertain, and this is also true of the actual time during which the sewage stays within the harbor limits. An additional consideration is the probable existence of a rather strong bacterial culture in the waters of the harbor. It is quite usual to see a marked brownish floc in the waters of Newark Bay, similar in appearance to that of activated sludge. More reliable data are needed on the oxygen demand of sewage in harbor waters, but with the limited information available it seems that Adeney's estimates for the oxygen requirement of settled sewage in New York Harbor may be accepted for the present. In the following computations, therefore, the oxygen demand for sewage entering Newark Bay has been taken at 570 cu. cm. of oxygen per gallon of sewage.

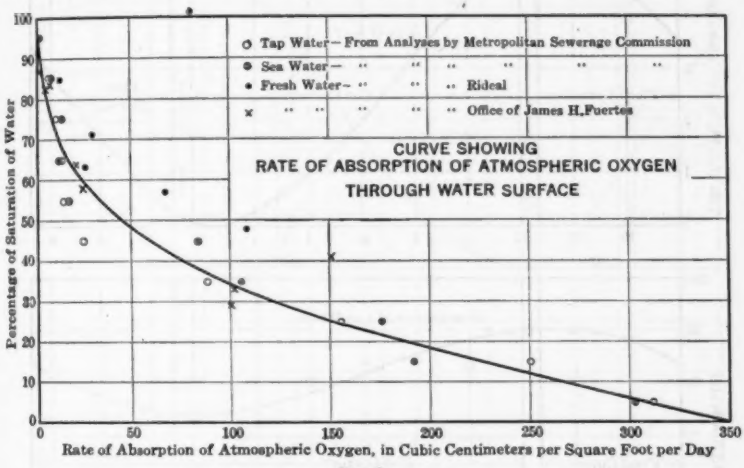
Absorption of Atmospheric Oxygen by Water

The differences of opinion regarding the quantity of oxygen absorbed by water have hinged largely on whether or not oxygen dissolved by the top layers could stream or be diffused or otherwise distributed throughout the body of water at lower depths. In his report to the Board of Estimate and Apportionment of New York City in 1911, Earle B. Phelps, Affiliate, Am. Soc. C. E., showed that if Ficks' law of diffusion was applicable, oxygen would not penetrate to any great depth, and that little oxygen could be absorbed by the water. He also estimated, in the same report, that the upper 12 ft. of the harbor waters were thoroughly mixed every 1.1 hours by the influence of tides, wind, shipping, etc. As a result of his experiments, Adeney held that dissolved oxygen would stream from the top to the bottom of the liquid, maintaining a nearly uniform percentage of saturation throughout the depth of the water.

The latter view does not seem to be inconsistent with the results obtained by the Metropolitan Sewerage Commission, which indicated, as a rule, no marked and general difference in the oxygen values near the surface and those toward the bottom. In Newark Bay, there seems to be little question but that dissolved oxygen is uniformly and rapidly mixed throughout the depth of the water. The tidal water coming in through the deep channels of the Kills is spread out like a fan over the shallow flats of the Bay. It is further mixed by the close-standing piles of the railroad trestles crossing

the Bay, and by the uneven bottom caused by ship channels and obstructions.

The quantity of oxygen capable of being absorbed will depend on the temperature, salinity, and percentage of saturation of the liquid. Water devoid of dissolved oxygen when exposed to the air will absorb oxygen rapidly at first, the rate of absorption decreasing gradually to a low value when the capacity of the water has been reached. A number of analyses made by the Metropolitan Sewerage Commission, Mr. Rideal, and the writer, have been recomputed,



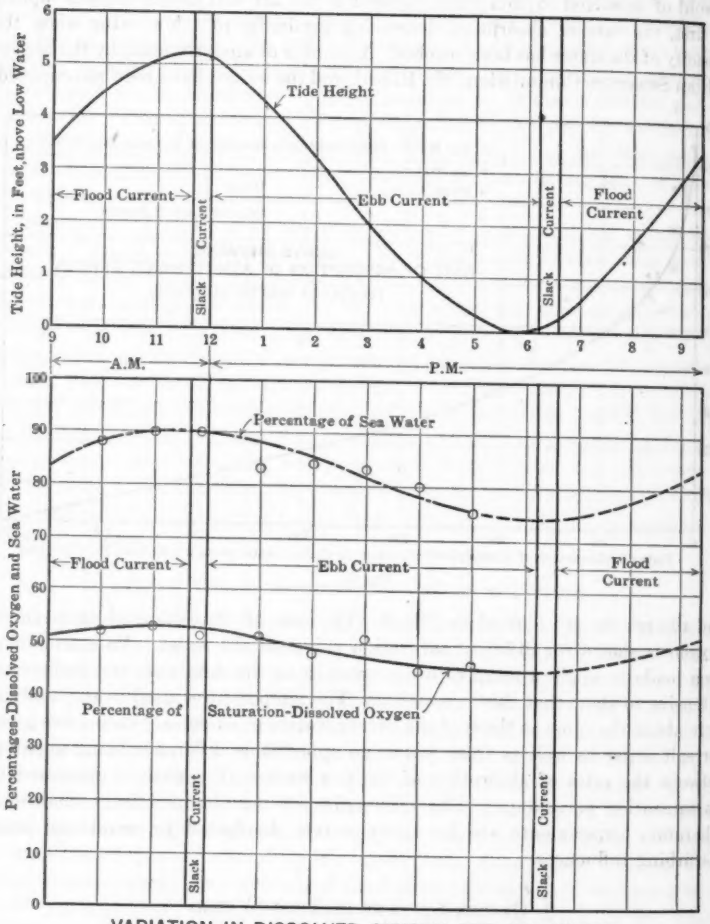


FIG. 3.

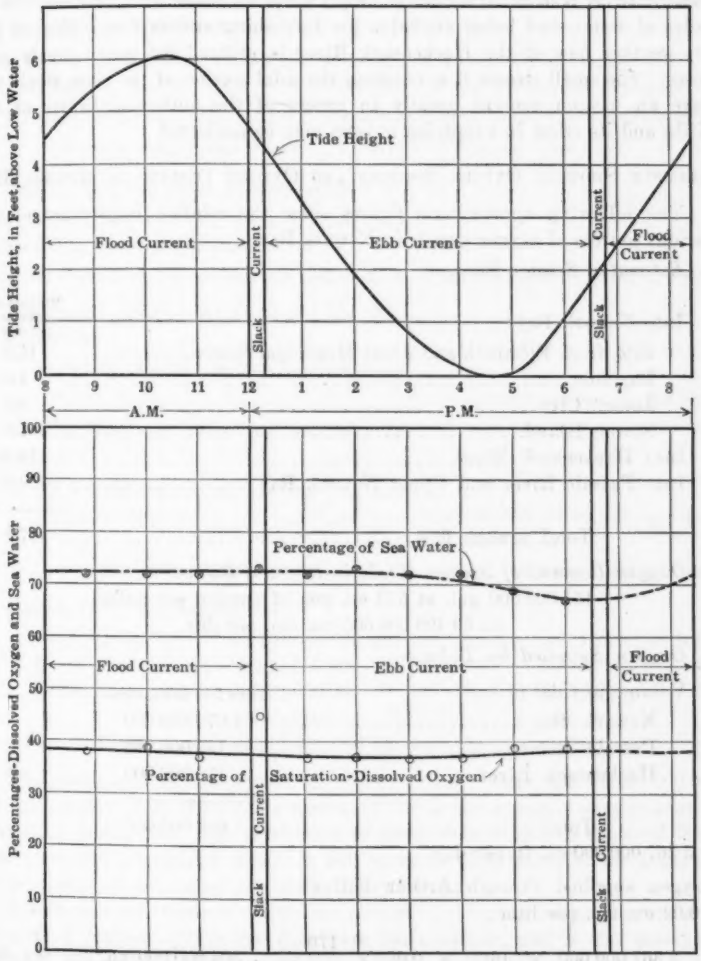
and the results are plotted in Fig. 3. The rate of absorption of atmospheric oxygen is shown for different saturation values of the water. No attempt has been made to apply a temperature correction as the data were not sufficiently extensive to show that this is necessary. The temperatures used in the analyses were about the same as those of the harbor waters in summer. Values are given for salt water as well as fresh water, no appreciable difference being apparent between the rates of absorption of the two waters when each is estimated on its saturation percentage. The values given being obtained from small-scale laboratory experiments are for quiet waters unaffected by wind and other disturbing influences.

OXYGEN SUPPLIED BY TIDAL WATERS

One of the interesting and rather surprising facts disclosed by investigation was that the tidal waters flowing into Newark Bay through Kill van Kull and Arthur Kill supply little oxygen for the purifying processes taking place in the Bay. It was found from an examination of the reports of the Metropolitan Sewerage Commission that from 106 analyses of flood currents and 104 analyses of ebb currents in Kill van Kull during 1911, 1912, and 1913, the excess of oxygen in the flood currents over that in the ebb currents was only 0.10 cu. cm. per liter, or less than 1.5% of the saturation value.



Analyses made by the writer, during 1920, covering a tidal cycle in Kill van Kull and in Arthur Kill, at Elizabeth, are shown graphically in Figs. 4 and 5. The excess oxygen carried by flood currents over that carried by the

VARIATION IN DISSOLVED OXYGEN AND SEA WATER IN THE WATERS OF KILL VAN KULL AT BERGEN POINT LIGHT, OCT. 15, 1920

FIG. 4.

ebb currents was found to be 0.16 cu. cm. per liter in the case of the Kill van Kull and 0.02 cu. cm. per liter in the case of Arthur Kill. It may be noted that the quantity of oxygen supplied to the Bay from this source is of minor importance.

VARIATION IN DISSOLVED OXYGEN AND SEA WATER IN THE WATERS OF ARTHUR KILL AT ELIZABETH, N. J. OCT. 13, 1920

FIG. 5.

Oxygen Supplied by Natural Stream Flow

Periods of low saturation in the harbor waters correspond generally with low stream flows in the inflowing rivers. Part of the dry-weather flow of the Passaic River is diverted for water supply purposes, about 81%, or about 770 sq. miles of water-shed being available for furnishing stream flow. Most of the dry-weather flow of the Hackensack River is utilized for water supply purposes. The small stream flow entering the tidal section of the river would not have an oxygen content greatly in excess of the outflowing water at the Kills, and its effect in supplying oxygen may be neglected.

Example Showing Oxygen Sources and Oxygen Demand in Newark Bay

The following approximate figures show the relative importance of the various sources of oxygen supply in Newark Bay.

Estimated Sewage Flow.—

Into Newark Bay:	Millions of gallons per day.
50% from Elizabeth and Joint Municipal Sewer	15.0
Bayonne	1.0
Jersey City	6.0
Staten Island	1.0
Into Hackensack River	14.0
Into Passaic River and Upper Newark Bay	120.0
Total sewage flow	157.0

Oxygen Demand of Sewage While in Bay and Rivers.—

157 000 000 gal. at 570 cu. cm. of oxygen per gallon
= 89 490 000 000 cu. cm. per day.

Oxygen Supplied by Tides.—

Volume in tidal prisms:	Cubic feet per cycles.
Newark Bay	1 070 000 000
Passaic River	195 000 000
Hackensack River	418 000 000
Total	1 683 000 000

or 3 367 000 000 cu. ft. per day.

Oxygen supplied through Arthur Kill at 0.02 cu. cm. per liter:

$$3\,367\,000\,000 \times 16\% \times 0.02 \times \frac{170}{6} = 304\,000\,000 \text{ cu. cm. per day.}$$

Oxygen supplied through Kill van Kull at 0.16 cu. cm. per liter:

$$3\,367\,000\,000 \times 84\% \times 0.16 \times \frac{170}{6} = 12\,800\,000\,000 \text{ cu. cm. per day.}$$

Total oxygen from tides..... 13 104 000 000 cu. cm. per day.

Oxygen Supplied by Rivers.—

Passaic River.—The dry-weather flow is taken at 0.2 cu. ft. per sec. per sq. mile of water-shed not used for water supply. The oxygen content is assumed to be 5.2 cu. cm. per liter at Paterson Falls and 1.8 cu. cm. per liter at Kill van Kull, or a difference of 3.4 cu. cm. per liter:

770 sq. miles at 0.2 cu. ft. per sec. $\times$ 86 400 = 13 310 000 cu. ft. per day.
13 310 000 $\times$ 3.4 $\times$ 28.32 = 1 280 000 000 cu. cm. of oxygen per day.

Hackensack River.—The entire dry-weather flow is taken for water supply:

Total oxygen from rivers = 1 280 000 000 cu. cm. per day.

Oxygen Supplied from Atmosphere.—*

Passaic River.—At 0% of saturation and 40 600 000 sq. ft. of water surface:

40 600 000 at 345 cu. cm. per square foot = 14 007 000 000 cu. cm. per day.

Hackensack River.—At from 5% to 40% of saturation:

89 000 000 sq. ft. at 166 cu. cm. per square foot..... = 14 774 000 000 cu. cm. per day.

Newark Bay.—At from 5% to 35% of saturation:

227 700 000 sq. ft. at 184 cu. cm. per square foot..... = 41 900 000 000 cu. cm. per day.

Total oxygen from air..... 70 681 000 000 cu. cm. per day.

Oxygen from All Sources.—

From tides.....	13 104 000 000 cu. cm. per day =	15.4%	of total
From rivers.....	1 280 000 000 " " " " =	1.5%	" "
From atmosphere.	70 681 000 000 " " " " =	83.1%	" "
Total	85 065 000 000 cu. cm. per day =	100	%

The estimated oxygen demand of the entering sewage was 89 490 000 000 cu. cm. per day, 95% of which is accounted for in the apparent oxygen sources previously mentioned. The agreement is closer than might be expected from the extent of the available data. It will be noted that 83.1% of the apparent oxygen supply is estimated as coming from the air.

An attempt was made to apply this method of computation to the whole of New York Harbor. Complete data were not available, and it was necessary to make a number of approximations. Table 1 is given not because it is believed to be accurate in all its details, but because it throws an interesting light on the relative importance of the purifying agencies acting on the harbor waters.

It is recognized, of course, that the source of oxygen dissolved in water is from the air, although agreement is not general as to the rate at which this

* Absorption values are taken from Fig. 3.

takes place. Passing out from the harbor to the ocean, organic matter is diluted with such large volumes of water and spread over such a large area that the depletion in oxygen is not noticeable. The distinction between oxygen supplied from the tides and that from the air is relative only, depending on the areas considered. If the included area is taken far enough from the sources of pollution, the effects of oxygen carried by the tides are of little relative importance, as all oxygen consumed by the waters in the area is made up by absorption within the limits chosen. The area available to absorb oxygen and maintain dissolved oxygen in the waters near the sources of pollution depends chiefly on the distance and area reached by direct tidal currents and, therefore, on the volume of tidal flow passing these points. The intermixture of the direct tidal currents with waters in the areas immediately beyond their reach makes additional absorption areas available. These latter areas are polluted to a lesser degree, and, therefore, the unit rate of oxygen absorption is less. The extent of these areas will depend on the characters of the tidal currents, the tidal over-run, and other conditions difficult to define.

TABLE 1.—Absorption of Atmospheric Oxygen in New York Harbor in 1920.

Section.	Area of water surface, in million square feet.	Estimated minimum percentage of saturation of dissolved oxygen, in 1920.	Oxygen Absorbed from Air:	
			Cubic centimeters per square foot per day.	Million cubic centimeters per day.
Upper Bay	542	25	152	82 500

Long Island Sound, Throggs Neck-Pelham	489	80	6	2 940
Total apparent oxygen absorbed from atmosphere				423 150

In the case of New York Harbor, the waters of the Lower Bay are still well saturated with oxygen, indicating that beyond this point oxygen is absorbed at a low rate, presumably over large ocean areas. Table 1 indicates to what extent the oxygen that may be absorbed by waters, depleted to the extent of the harbor waters, compares with the estimated oxygen demand of the sewage from the Metropolitan District. The minimum saturation values found in the harbor waters are used, as it is believed that they comply with the basis of the absorption curve more than average values which include high figures due to the disturbing influence of winds, etc. Most of the saturation values

used are estimates based on the minimum values published in the 1917 Report of the Board of Estimate and Apportionment of New York City. The absorption values of atmospheric oxygen are taken from Fig. 3.

The oxygen content of the fresh water of the rivers flowing into the harbor is not materially different from that of the waters of Long Island Sound and the ocean at Sandy Hook, so that the influence of the oxygen carried by them may be neglected. If the total sewage flow of the Metropolitan District is taken as 800 000 000 gal. per day, the 423 150 cu. cm. of oxygen per day given in Table 1, represents 529 cu. cm. of atmospheric oxygen per gallon of sewage utilized by the organic matter in the sewage while it is within the harbor limits. This is about 16% greater than the estimate of the Metropolitan Sewerage Commission for the oxygen demand of New York sewage and about 7% less than that of Adeney as given previously. This seems to indicate that nearly the entire oxygen demand of the sewage in the harbor waters can be taken care of by direct absorption from the air. From this, it seems reasonable to conclude that the percentage of saturation of the harbor waters at any point will be lowered to such a value that the oxygen absorptive powers of the waters at this percentage of saturation will equal the oxygen demand of the fermenting organic matter in these waters.

A similar computation was carried out for the tidal section of the Elizabeth River. This is a small, badly polluted stream flowing into Arthur Kill. It has a water surface of 1 028 000 sq. ft., and during the four tests (Table 2), the stream flow ranged from 1.6 to 10 million gallons per day and the percentage of saturation of dissolved oxygen from 12 to 32 per cent. The polluting sewage was estimated at 800 000 gal. per day. Table 2 shows the results of the four tests.

TABLE 2.—Sources of Dissolved Oxygen in the Elizabeth River.

Date, 1920.	Oxygen Supply, in Million Cubic Centimeters per Day, from:				Percentage of estimated oxygen demand.
	Stream flow.	Tidal flow from Arthur Kill.	Absorbed from atmosphere.	Total.	
June 30	30.2	158	267	455	100
July 29	17.6	240	267	524.6	115
August 12	131.0	146	123	400	88
October 22	50.0	293	227	570	125
Average				487.4	107

Although there is some variation, due possibly to inaccuracies in the various estimates made, the results in general tend to confirm the applicability of the method of computation.

To sum up the questions discussed, the evidence seems to indicate that the oxygen demand of polluted harbor waters, when not supplied from other sources, is satisfied as far as possible by direct absorption from the air and that the dissolved oxygen in the waters will be depleted until the rate of oxygen absorption from the air equals the rate of oxygen demand of the fermenting organic

matter; that is, the area of the water surface available to absorb oxygen from the air appears to be the principal factor in controlling the condition of polluted harbor waters. The volume of water in the harbor and tidal currents, although of tremendous importance in mixing the waters and distributing the polluting material over large areas, seems to be secondary to the ability of the waters to absorb oxygen directly from the air.

Data on the oxygen demand of sewage in the waters of New York Harbor and for the construction of an absorption curve are not as complete as might be desired. It is believed, however, that the values given by the writer are sufficiently close to actual conditions to bear out at least the underlying ideas presented. With more extensive data, it might be possible that the methods indicated will permit a reasonably accurate estimate to be made of limiting quantities of sewage which the harbor will receive without the production of an active nuisance, or to predict the extent of depletion in the dissolved oxygen content for definite quantities of polluting material.

DISCUSSION

W. C. PURDY,* ESQ. (by letter).—This paper, dealing with re-oxygenation of the polluted waters of New York Harbor, is of much interest, but sufficient controlled observations do not seem to be available on which to base definite conclusions. Other factors than wind action may be responsible for great fluctuations in the oxygen content of the harbor waters. The author mentions three sources of oxygen, namely, the sea water, water of tributary streams, and the atmosphere. Granting that oxygen undoubtedly does accrue to the harbor waters from all these sources, the writer, who is a biologist, desires to call attention to another probable source.

The author makes no mention of the presence—or the absence—of aquatic plants in the waters studied. Unless the situation is totally different from that which is ordinarily found along the seaboard, especially in the more shallow waters, there is, in all probability, a considerable growth of various algæ or "sea weeds", green, brown, or red in color, also of eel-grass, and of *Ceratophyllum* or "fish-moss", commonly used in aquaria. Finally, it is practically certain that diatoms and other of the microscopic plants are present.

In the presence of sunlight, practically all these plants give off oxygen as a waste product of their metabolism. This oxygen, which is produced under water, is naturally taken up largely by the surrounding water, until, in some cases, the latter becomes supersaturated with oxygen. It would be interesting to have a detailed record of the amount of sunlight exposure on such days when large increases in oxygen content was noted between morning and afternoon observations. A close correlation of increase of dissolved oxygen and sunlight available would no doubt be observed.

The net result of this production of oxygen by submerged plants is sometimes very noticeable, not only in the oxygen content of the water, but also in the evident increase in the capacity of this water to dispose of organic matter. In the investigation of the Potomac River,† it was found that aquatic plants were largely responsible for the production of oxygen, sufficient to assist materially in the reduction of the 60 000 000 gal. of sewage emptied daily into the river by the City of Washington.

In an unpublished study of the effect of diatoms (a plant of microscopic size) on the oxygen content of water in the Ohio River, it was found that when diatoms were present to the extent of about 68 parts per million (by volume) per cubic centimeter of water, the oxygen content increased considerably more than in the same water from which the diatoms had just been removed by filtering. A similar increase was noted over the oxygen content of a third sample of the same water which contained the diatoms, but was kept in darkness, under which conditions the plants could not function properly.

It is hoped that if plants—either microscopic or large—are present in a given water, these organisms will be credited with the oxygen that they must

* Special Plankton Expert, U. S. Public Health Service, Cincinnati, Ohio.

† U. S. Public Health Service, Hygienic Laboratory *Bulletin No. 104*, Supt. of Documents, Washington, D. C.

necessarily contribute to the water. It would seem illogical to take account of the layer of atmosphere above the water body, only one-fifth of which is oxygen, and ignore the visible producers of practically pure oxygen, which may, to a great extent, carpet the bottom in shallow waters, and those invisible but numerous oxygen producers, the microscopic algæ, which are usually present unless the water is too deep or too turbid for the light to penetrate.

ALLEN HAZEN,* M. AM. SOC. C. E. (by letter).—In drawing attention to the re-aeration of water in New York Harbor by the air, especially under the influence of wind action, the author has rendered a great service. This is an important matter, and sufficient attention has not been given to it in past studies of harbor conditions.

The water in the harbor receives the sewage of the city. This sewage contains a large quantity of organic matter which is decomposing and oxidizing. Oxygen is required in order that these processes may go on. If there is enough oxygen, the processes are comparatively unobjectionable and free from the production of nuisance; if, however, the supply of oxygen at any point is overtaxed, other processes set in, that are offensive. The presence or absence of oxygen corresponds closely with conditions that are inoffensive or offensive, and it is essential, therefore, for the comfort of the communities about the harbor, that there should be enough oxygen in the water.

The air is 21% oxygen. Water dissolves only about 2% of its volume of air. Ordinarily, the water coming down the Hudson River and the sea water coming in from the ocean are saturated, or nearly saturated, with oxygen.

The quantity of water in each tide is definitely known, and the new water forming a part of it can be computed approximately. The computation is approximate, because the percentage of new water in the water coming back with the tidal flow must be estimated, and chemical analysis furnishes a fairly definite basis for this estimate. The new water entering the harbor from the sea and from the river, estimated in this way, is equal to a continuous flow of about 76 000 cu. ft. per sec.† When the rivers are in flood, the quantity of fresh water entering the harbor is greatly increased and tends to take the place of and keep out an equal volume of sea water. When the flows of the rivers are low, the sea water enters in full quantity, and almost the entire mass of water in the harbor is composed of it. As an annual average, approximately one-third of the new water is from the rivers and two-thirds from the ocean. River water carries somewhat more oxygen per unit than sea water, and cold water in winter carries more than warmer water in summer.

Without attempting refinements, the average quantity of oxygen carried by the new water, at an average temperature of 50°, is about 89 lb. per 1 000 000 gal. This is increased to 110 lb. in winter and decreased to about 65 lb. at 68°, which may be taken as summer temperature for sea water entering the harbor.

New water at the rate of 76 000 cu. ft. per sec. is equivalent to 49 200 000 000 gal. daily. The average quantity of dissolved oxygen carried by this new

* Cons. Engr. (Hazen, Whipple, and Fuller), New York City.
† *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), p. 2094.

water is approximately 4 400 000 lb. per day as an annual average. The summer quantity amounts to 3 200 000 lb. per day.

The demand for oxygen is most rapid in summer, because oxidation goes on more rapidly then, and changes take place in the harbor which at other seasons are completed at remote places where other supplies of oxygen are available. The summer period, therefore, is the critical time, and summer quantities only need be considered.

The summer quantity, as estimated, is equal to 0.4 lb. daily (or 180 grammes) for each person now living in the Metropolitan District, and is sufficient to oxidize the sewage of a much larger population. In order to utilize it to its fullest extent, however, it is necessary that the sewage be completely mixed with all of it. Such a distribution is not obtained and is not possible. There are places of local concentration of sewage and, at these places, the supply of oxygen is drawn lower than elsewhere.

The secondary source of oxygen, as the author has pointed out, is the atmosphere; he thinks this is the greatest source.

When the water in the harbor is saturated with oxygen, there is no absorption of oxygen from the air by it. As soon as the water in any part of the harbor becomes less than saturated, the absorption of oxygen from the air begins, and the oxygen thus absorbed adds to the supply otherwise available. The absorption of oxygen from the air by water, other things being equal, is directly proportional to the reduction below the saturation point. If twice as much oxygen is used by the sewage in any locality, there will be twice the degree of depletion in that locality, and, with it, the rate of absorption from the air will be doubled.

Oxygen derived from the air, therefore, is greatest in amount at exactly those places where the need of it is greatest; and for this reason the value of the oxygen derived from the air is of the greatest value in keeping the harbor water sweet.

Some early studies on oxygen absorption started with the assumption that oxygen absorbed by the surface layer of water must be carried to lower layers of diffusion. If this was the case, the slowness of the diffusion process would limit the amount of oxygen that could be absorbed in this way. Fortunately, there are other means of distributing the oxygen. The tides keep the water in the harbor always in motion, and there is a mixing that is many times more powerful than diffusion in carrying the re-aerated water below the surface, and in bringing water that needs aeration from below to the surface, at which it only can be aerated. This movement due to tidal action is always going on.

Wind action is still more potent when available, but is intermittent in its action. A heavy wind brings all the water into contact with air, and results in a great increase in the rate of absorption. This increase is fairly comparable to that which takes place when a bellows is applied to a bed of coals.

The absorption of oxygen, other things being equal, is greater in shallow parts of the Bay, where the surface exposed, in proportion to volume, is greater than elsewhere, as, for instance, in Newark Bay.

How far the absorption of oxygen from the air by the exposed surface of the harbor will add to its capacity to receive and dispose of sewage, is not known. The matter is progressive; as the need of oxygen in any part of the harbor increases, the rate of absorption increases with it. Only the future, with greater populations, will disclose the limit.

In the meantime, such studies as that presented by the author, bring to notice these important fundamental actions and will tend to a better understanding of what is taking place.

WARREN R. BORST,* ESQ. (by letter).—The author's observations on the fluctuation of dissolved oxygen values in the Arthur Kill, at Elizabeth, N. J., are of special value and interest to the Borough of Richmond, especially so, as the observations made in waters adjacent to Staten Island shores seem to confirm the investigations with regard to the absorption of oxygen made at the West Brighton Sewage Experiment Station, in 1916, under the direction of the President of the Borough of Richmond. However, it would not seem possible to determine a quantitative relation between wind velocities and dissolved oxygen content, unless it was possible to determine the depth of the influence of wave action caused by the wind. From past experience and data at hand, it would seem that the depth to which the oscillation penetrates below the surface of the water depends on the violence with which the surface is disturbed.

The experimental work in the absorption of oxygen at the West Brighton Sewage Experimental Plant verified, in a large tank, the results which Adeney found to be true in glass tubes, namely, that the oxygen gravitated downward so rapidly that it was impossible to determine the rate, and, for practical purposes, in the writer's observations, was considered instantaneous for the full depth of 5½ ft. The velocity with which this diffusion or gravitation of oxygen takes place will be better appreciated by the following statement taken from the Fifth Report of the Royal Commission on Sewage Disposal of Great Britain:

"Hüfner in his work on the diffusion coefficients of gases in water met with the phenomenon of the comparatively rapid downward passage or streaming of the dissolved gas, and, in consequence, found that it was impossible to study the diffusion of gases in water when the gas was placed above the liquid, and he was compelled to employ for his experiments a thin plate of the porous mineral hydrophane to hold up a column of water in an experimental tube, and so to provide the means of introducing the gas at the bottom of the water and of studying its upward diffusion through the water.

"Experiments for determining the amount of dissolved oxygen absorbed by sewage from fresh water and sea water, as well as the rate of re-aeration of a water with its dissolved oxygen content depleted by sewage, were made in the four tanks, each of which had dimensions 25 ft. long, 6 ft. wide, and 6 ft. deep.

"These experiments may be subdivided as follows:

"1. Dissolved oxygen absorbed in dilutions of sewage with fresh water:
(*a*) Without surface agitation.
(*b*) With slight surface agitation by two electric fans.

* Asst. Engr., Borough of Richmond, West New Brighton, N. Y.

"2. Dissolved oxygen absorbed in dilution of sewage with sea water:
(*a*) Without agitation.
(*b*) With slight surface agitation by electric fans.
(*c*) With the surface agitated, making a wave, without splashing, about 4 in. high.

"3. Rate of re-aeration produced by surface agitation in a mixture of sewage and sea water containing no dissolved oxygen."

In the writer's observations, simultaneous samples, taken at each foot of depth through ¼-in. galvanized pipes projecting through the sides of the tank, in almost every instance, gave the same amount of dissolved oxygen, the amount depending solely on the violence of the agitation at the surface.

When the surface was quiet, the absorption of oxygen was small and seemed to be due to a change in temperature. The slight ripple of the surface obtained by the wind from two electric fans was sufficient to produce considerable absorption of atmospheric oxygen. A still greater absorption of oxygen was obtained by disturbing the surface with a 4-in. wave movement, produced (without splashing) by a vertical reciprocating action of a horizontally disposed furring strip located at the center and at right angles to the length of the tank.

It was noted that in fresh water, salt water, or in sewage, diluted with either fresh or salt water, the downward diffusion or gravitation of oxygen was practically instantaneous.

Neither the temperature of the water, nor the percentage of dilution of the sewage seemed to be factors in the rapidity with which this gravitation of the oxygen took place. The more violent the agitation of the surface, the greater the amount of dissolved oxygen was present. The amount of oxygen capable of being absorbed depended on the temperature, salinity, and percentage of saturation of the liquid at the beginning of the agitation.

The tanks used were 6 ft. in depth, and the observations were limited to a depth of 5½ ft. From extensive studies made at Duluth, Minn., Milwaukee, Wis., New York City, and other places, it would appear that as the effect of the wave action may extend to a depth of from 30 to 40 ft., that the depth to which this gravitation takes place would be practically the same.

In the experiments mentioned, the change of temperature of the liquid was not rapid. In many cases the temperature of the liquid in the tanks was raised to 25° cent. (77° Fahr.) by heating with exhaust steam. The temperature of the atmosphere was 10° cent. (50° Fahr.). In such cases, the temperature of the liquid did not reach the temperature of the atmosphere during the 24 hours in which the observations were made. At the bottom, the temperature was from ½° to 2° warmer than at the surface.

The rate at which the dissolved oxygen was reduced by the demand of the organic matter present in the liquid, depended on the temperature maintained in the tank. Where the temperature of the liquid was reduced from 20° cent. to 13° cent. within 24 hours, the rate at which the dissolved oxygen was reduced was practically the same as for liquid that was maintained at 20° cent. throughout the 24 hours. Where the temperature was higher than 20° cent., the rate at which the dissolved oxygen was reduced was much greater, but at no

time was the reduction greater than the oxygen obtained from the surface when agitated by a ripple ½ in. in height.

In the case of the dilution of 1 part of sewage to 20 parts of fresh water with a ½-in. ripple, it was found that after the fourth hour the rate of absorption of atmospheric oxygen was about 0.18 parts per million per hour. With salt water, the rate was 0.085 parts per million per hour.

Another observation was made with a mixture of sewage and salt water, which was devoid of oxygen. The surface was agitated with a 4-in. wave and, at the end of 4 hours, it was found that the dissolved oxygen, at all depths, had increased from 0 to 6.56 parts per million, or at the rate of 1.64 parts per million per hour. At the end of the fourth hour, the agitation was stopped, and the mixture allowed to remain quiet for 20 hours. At the end of this period, the dissolved oxygen had decreased to 4.50 parts per million, or at a rate of 0.1 parts per million per hour.

Diagrams and tables containing the detail of the studies on the absorption of oxygen were published in a "Report on Sewage Experimental Investigations at West New Brighton, Staten Island, N. Y.", by the writer, and issued by the President of the Borough of Richmond, City of New York.

The author concludes that the rapid increase of dissolved oxygen in polluted tidal waters, when roughened by the wind, is caused by the increased area exposed to the air. The experiments of 1916 at West New Brighton seem to indicate that the rapid increase of dissolved oxygen in polluted tidal waters when roughened by the wind, is due to the oscillation of the waves breaking through the layers of the water to various depths.

KENNETH ALLEN,* M. AM. SOC. C. E. (by letter).—The extent to which polluted waters are improved by re-aeration is a matter of much importance to towns along the shores. It requires little acquaintance with the subject to be impressed with the difficulty of arriving at any reliable quantitative solution of the matter so largely affected, as it is known to be, by disturbances of the surface and the overturning caused by the wind, currents, changes of temperature, etc.

In general, the pollution at any point in a stream depends on (*a*) the dissolved oxygen at the source of pollution; (*b*) the oxygen demand of the polluted water at that point; (*c*) the amount of re-aeration occurring between these two locations; and (*d*) the depletion of dissolved oxygen that takes place between the two points due to biological action.

The technique for the first two determinations is fairly specific and reliable, but estimates of the re-aeration and biological demand that take place in transit are subject to so many influences, and the laws governing these phenomena are either so obscure or else so lacking common endorsement, that such estimates or forecasts should be carefully weighed and expressed without too much assurance.

Temperature plays an important part in the percentage of saturation of polluted waters, so that cold-weather observations are of little value. Also, as stated by Mr. Gould, the effect of winds and currents is great, so that reliable results can only be had from the average of many tests.

* San. Engr., Office of Chf. Engr., Board of Estimate and Apportionment, New York City.

In tidal streams, there is a tendency to stratification, due to the lower specific gravity of the polluting sewage and the intrusion of the clean underrun from the ocean, so that dissolved oxygen determinations may be misleading if samples are not "representative". That this stratification may be greatly disturbed is quite apparent from cross-sections of salinity, as shown at different points in New York Harbor in the Final Report of the Metropolitan Sewerage Commission (salinity in this case being indirectly proportional to pollution). For this reason, any attempt to compute the oxygen supplied to the Upper Bay through The Narrows by the excess of the saturation on the flood over that of the ebb current, as the author has done with the Arthur Kill, would be misleading. Moreover, the constant change in conditions, due to tidal flow, introduces further complications. The dilution in a land-locked tidal basin is the ratio of the tidal prism to the volume of sewage entering during a tidal cycle. Other things being equal, a shallow bay, such as Jamaica Bay, has the advantage over a deep body of water, in that a larger proportion of its volume is discharged to the ocean with every ebb; for although the ultimate dilution is the same, at high tide a larger proportion is of new and, presumably, better oxygenated water.

The problem of re-aeration has been dealt with in an orderly way by Mr. Gould, and his results are presented in a clear concise manner. Fig. 3, on which computations of re-aeration are based, furnishes the information required in a convenient form. The writer, however, has been unable to check the results plotted from experiments of the Metropolitan Sewerage Commission, and, as the matter is of considerable importance, he hopes that the author will describe more fully, in his closure, how he arrived at these and his original experimental data. This is particularly desirable as the values he gives for re-aeration are considerably in excess of some others that have been published.

The absorption of oxygen per unit of surface is a most convenient figure to use, but in looking over the results of various experimenters it has been difficult or impossible to interpret them in this form without assumptions which do not seem to have sufficient sanction.

With regard to the rôle played by absorption from the air, E. B. Phelps, Affiliate, Am. Soc. C. E., states*:

"With the deep and relatively quiescent waters of New York Harbor re-aeration was found to be almost a negligible factor, the capacity of such a body of water to oxidize pollution is practically limited by the amount of available oxygen brought in from the ocean with each tide.

"In rivers the conditions are reversed, the initial volume of available oxygen is small compared with the total capacity of the stream to oxidize pollution. Re-aeration in rivers is the chief factor."

Adeney† also states, "when the atmosphere is calm and saturated with moisture, the rate of re-aeration will be practically at zero", but he points out further that this rule does not apply to other conditions and that "the rate of re-aeration must therefore be an extremely variable quantity".

* Reprint No. 214, Public Health Reports.

† Report, Metropolitan Sewerage Comm., 1912, p. 81.

As a matter of fact, the surface of the Upper Bay is nearly always more or less disturbed if not actually broken up by waves, and it has been shown by Messrs. Adeney, Ellery, and Borst that this increases the rate of re-aeration to a marked extent. This provides a sanction for using higher rates in practice than those determined experimentally with still water. Professor Phelps has estimated the effect of mixing due to vessels, wind, and tide, on re-aeration in New York Harbor, but, after all, the writer thinks it will be admitted that little is known about the actual rate of re-aeration in a specific case, for as yet there is no reliable measure of the influence of wind or humidity, either of which may safely be assumed to overshadow any rates for still water.

Dr. Hugh S. Cumming, of the U. S. Public Health Service (now Surgeon-General), found* in September, 1913, that in flowing from Washington to Fort Foote, in five days, the dissolved oxygen of the Potomac River was reduced from 8.13 to 4.88 parts per million. The oxygen demand of Washington sewage, however, as determined for that month, was 7.14 parts per million, which would have left only 0.99 parts per million on reaching Fort Foote. The remainder of 3.89 parts per million was made up by re-aeration.

A matter which is usually not considered, but which may have an important bearing on the oxygen content of a stream, is the regeneration of this gas by plant life. The plankton that abound in the tidal flats of the Potomac River have been estimated to furnish 17.7 lb. per acre daily of oxygen to the waters, under favorable conditions. It was computed by Mr. W. C. Purdy, in connection with the investigation of Dr. Cumming referred to, that with an oxygen demand of 300 parts per million, 1 000 000 gal. of Washington's sewage would require 2 500 lb. of oxygen for its decomposition, so that this could be accomplished by the plankton of 141 acres of tidal flats.

"In other words, this flat will provide sufficient oxygen for the first 24 hours' natural purification of nearly 30 million gallons of Washington's sewage * * *. Purely physical re-aeration * * * is certainly not over 33 per cent. of the total effect, and if proper allowance could be made for the residual biological action upon cloudy days, perhaps 6 per cent. of full sunshine, this figure would be materially reduced."

Although re-aeration by plankton is seen to be a factor of importance in locations similar to the one cited, it was pointed out by the late Emil Kuichling, M. Am. Soc. C. E., in his testimony in the Passaic Valley Sewer Case, that in the transition from fresh-water to sea-water conditions, or *vice versa,* these minute forms of vegetable life do not prosper, and it is probable that their influence in providing oxygen to such tidal bodies of water as are found in New York Harbor is not great.

Mr. Gould has estimated the quantity of dissolved oxygen available for the oxidation of the polluted waters of Newark Bay and indicated how this method may be applied to New York Harbor. Such computations aid in arriving at fair ideas of relative values and are generally illuminating, but much more definite knowledge of the influence of salinity, depth, wind, and humidity is necessary in questions of re-aeration, and regarding the draft on this supply by decomposing sludge beds, in order to predict results with con-

* U. S. Public Health Service, Hygienic Laboratory *Bulletin No. 104.*

fidence. Adeney, for instance, finds a rate for re-aeration in sea water 2.7 times that in fresh water, with an increase proportional to the depth to at least 6 ft., but leaves one in doubt as to greater depths, whereas Phelps makes the rate nearly inversely as to depth and directly proportional to the depletion, with corrections for the effect of mixing. As to the effect of sludge deposits, also, there is a wide divergence of opinion.

Taking Adeney's results, as applied to the Upper Bay during average August conditions, as well as can be told, and 1920 populations tributary to the Bay, the supply and demand of oxygen may be compiled as follows, ignoring, for the time, any demand by the underlying beds of sludge.

Population.—The population tributary to New York Upper Bay, assuming that sewage entering the Hudson River above Yonkers, N. Y., is oxidized before its arrival, is as follows:

New York City	5 231 100
Westchester County	182 600
New Jersey	1 671 200
Total	7 084 900

Water Areas.—

Dissolved Oxygen Supplied by Re-aeration.—Adeney states this to be at the rate of 0.03 cu. cm. per liter per hour, for completely de-oxygenated fresh water, increasing in proportion to the salinity to 0.08 cu. cm. per liter for sea water, and that this holds good for depths of 6 ft. If this is arbitrarily assumed as a limit and also that the rate of re-aeration is directly proportional to the depletion found in the different bodies of water, it is found that:

Pounds of oxygen absorbed from the atmosphere in 24 hours = 0.01285 [0.03 + 0.05 (proportion of sea water × depletion of DO)],

the first coefficient being the pounds of oxygen contained in a column of water, 1 ft. square and 6 ft. high, containing 1 cu. cm. per liter.

Applying this to the problem in hand, Table 4 gives the following data.

TABLE 4.

Stream.	Percentage of sea water.	Percentage of dissolved oxygen.	Absorption coefficient, in pounds per square foot per day.	Oxygen absorbed per day, in pounds.
Hudson River	60.0	37	0.00049	206 000

Total	....	....	.....	863 100

The using of rates of absorption observed or suggested by Phelps and Ellery would give lower resulting values, whereas if the oxygen is carried by streaming to depths below 6 ft., the result would be increased.

Oxygen Demand of Sewage.—It is estimated that in 1920 the sewage of 5 413 700 persons in New York and 1 671 200 persons in New Jersey found its way to Upper New York Bay, or a total of 7 084 900 persons.

Langdon Pearse, M. Am. Soc. C. E., from many "tests on a large sewer serving 300 000 people, with no marked industrial wastes" finds* an equivalent of 0.22 lb. of oxygen per capita required for complete oxidation. The total demand for New York Harbor, therefore, may be estimated at 0.22 × 7 084 900 = 1 558 700 lb. We have, therefore,

Dissolved oxygen supplied by entering streams....	1 000 600 lb.
" " " " re-aeration	863 100 "
Total	1 863 700 lb.
Dissolved oxygen demanded of sewage.....	1 558 700 "
Excess supply	305 000 lb.

This would seem to indicate that, under August conditions at least, the main supply of oxygen to the Upper Bay is from the incoming streams. Also, that if the sewage was well diffused and if there was no draft on the oxygen

* See p. 451.

from underlying sludge, there would remain a balance of 304 400 lb., or one-sixth of the whole supply, to take care of further pollution. Additional proof is required, however, before a positive assertion as to true values can be made. It does not seem practicable, with the present knowledge of the subject, to estimate closely the influence of the wind and the stirring up of the water by steamships and ferries in re-aeration, or that of decomposing sludge deposits in de-aeration.

Nevertheless, such studies as that which the author has presented in his paper are most valuable aids in forming a correct opinion as to the present and future degree of pollution of a body of water, and great credit is due for the manner in which the subject has been prepared and presented.

H. W. STREETER,* Assoc. M. AM. SOC. C. E. (by letter).—This interesting paper deals with a problem which, although fairly simple in its fundamental underlying principles, is often extremely complex when an effort is made to apply these principles to a particular case. This is true not only of problems involving the re-aeration of semi-quiescent bodies of water, such as New York Harbor, but also of those which deal with the re-aeration of flowing streams, although in the latter case the factors entering into a solution of such problems are usually subject to more exact measurement. Whatever the type of the particular body of water under consideration, however, there are certain fundamental reactions which must be taken into account in determining its re-aeration capacity.

The changes which occur in the reserve dissolved oxygen content of all polluted bodies of water are governed by two reactions, each of which is progressive to a great extent and more or less independent of the other. The first of these is a progressive withdrawal of dissolved oxygen from solution in order to satisfy the oxygen demand of the oxidizible organic matter present in the water. This is essentially a bio-chemical reaction, requiring, for its progression, three elements: (*a*) oxidizible organic matter; (*b*) reserve oxygen in solution; and (*c*) oxidizing bacteria to act as carriers of the reaction.

The second reaction consists of a replenishment of the reserve oxygen supply through: (*a*) additional dilution water containing oxygen; (*b*) liberation of oxygen by certain forms of aquatic plants; and (*c*) physical solution of oxygen from the atmosphere. The addition of oxygen through the medium of dilution water is a matter of physical admixture, its relative importance in any case depending on the quantity of water added and the rate at which it becomes thoroughly mixed with the body of water under consideration. The addition of oxygen through biological re-oxygenation and atmospheric re-aeration, however, are both essentially progressive reactions, dependent, for their rates of progression, on a highly complex series of factors widely differing in the two cases. Thus, purely biological re-oxygenation, which has been referred to by Mr. Purdy as being a possible factor of great importance in the re-aeration of tidal estuaries near New York Harbor, depends on the presence of certain plants and their essential food elements, together with a highly complex series of environmental conditions favorable

* San. Engr., U. S. Public Health Service, Joliet, Ill.

to their activity. Among these, the influence of light has been emphasized by the work of Messrs. Purdy, Forbes, and others, which has shown that where biological re-oxygenation exists, its progress is greatly stimulated during daylight and greatly retarded during darkness.

Atmospheric re-aeration, however, is wholly a physical reaction, dependent primarily on the rate of solution of atmospheric oxygen at the water surface. This rate is a direct function of the proportion of oxygen in the overlying atmosphere and is likewise directly proportional to the deficit in oxygen saturation existing momentarily at the absolute surface.* If complete and absolute stagnation existed in the body of water under consideration, the quantity of oxygen absorbed directly from the atmosphere would be relatively small, since, as has been shown by Phelps,† once the extreme surface film of water became saturated with oxygen at the partial solution pressure existing under atmospheric air, the penetration of oxygen to lower strata would be dependent on diffusion, which is a slow process, once a gradient has become established. Available evidence indicates, however, that complete stagnation is practically never attained in natural bodies of water, even under conditions of extreme quiescence. Under these circumstances, the extreme saturated surface film is being constantly broken up and replaced by under-saturated particles of water, the presence of which, in contact with the atmosphere, restores instantly the solution reaction. The actual rate of solution, therefore, is governed largely by the rate of surface replacement of saturated water by partly de-saturated water. In flowing streams, where the replacement rate is extremely high, its progression is determined almost wholly by conditions influencing turbulence of flow, as extensive observations in the Ohio and Illinois Rivers, by the U. S. Public Health Service, have shown. In quiescent and semi-quiescent bodies of water, this rate, although undoubtedly lower than in flowing streams, is governed primarily by the same factor of vertical circulation, which, in streams, is termed "turbulence". The work of Sanborn‡ has indicated that wind action may be, and probably is, responsible for a large part of the variation taking place in the degree and depth of vertical mixing of quiescent bodies of water. Other things being equal, this factor is probably a far more important one in determining the re-aeration of bodies of water exposed to wind action, than the increased surface area gained by the water under such circumstances.

The point, which the writer particularly desires to emphasize, however, is that whenever a polluted body of water is exposed to progressive re-aeration, the processes of de-oxygenation and re-oxygenation proceed according to two virtually independent reactions. Whenever the rate of de-oxygenation exceeds that of re-oxygenation, the dissolved oxygen content will be progressively lowered until either a sufficient proportion of the initial oxygen demand has been satisfied or sufficient additional re-aeration capacity has been attained to

* This is merely a direct application of the law of velocity of solution derived experimentally by Noyes and Whitney, *Zeitschrift für Physik. Chemie*, Band XXIII (May, 1897), p. 689.

† Report on Pollution of New York Harbor, Board of Estimate and Apportionment, New York City, 1911.

‡ "A Theory of the Water Wave", *Transactions*, Am. Soc. C. E., Vol. LXXI (1911), p. 284.

bring about an equalization or actual reversal of the two relative rates. From this point, a recovery of reserve oxygen sets in, disturbed only by the introduction of fresh pollution or by modification of the re-aeration rate. In streams, such as the Illinois River which receives the greater part of its pollution at a point near its head-waters, the influence of changes in the balance of these two reactions on the retrogression and subsequent recovery of reserve oxygen by the river may be traced for many miles below a point of major pollution.

Interpreting the author's data from the standpoint of the foregoing principles, it is evident, first of all, that a true measure of progressive re-aeration in bodies of water similar to New York Harbor, whether from biological or atmospheric sources, cannot be obtained without taking into account both the initial and residual oxygen demand of these waters, the difference, when corrected for changes in dilution, representing the amount which has been satisfied during the particular cycle of observations. If the dilution factor finally becomes sufficiently great in the outer harbor to reduce the residual oxygen demand to a value so low that it cannot be measured, the problem is virtually indeterminate, as the base line necessary for measuring the quantity of oxygen demand actually satisfied (and, consequently, the quantity of oxygen absorbed from solution), has been destroyed. It would hardly appear, however, that this need necessarily be the case, provided sampling stations are carefully selected, with the end previously stated in view, and provided, further, that determinations of residual oxygen demand at these stations can be corrected for the demand of the diluting sea water.

A further complication in calculations of this kind lies in the importance of the time factor in all the progressive re-actions which have been noted. In a flowing stream, this factor may be determined with a fair degree of accuracy, but, in tidal bodies of water, the problem is often rendered almost hopelessly complex by the vagaries of tidal movements, accompanied in some cases by marked and sudden changes in dilution. Where the age of a given body of polluted water, as measured by the time elapsed between entering and leaving the harbor waters, is relatively long, say, 5 to 10 days, the error involved in approximate assumptions bearing on the time factor is not great, but where it is so small as to fall within limits of 2 or 3 days, the error involved in such assumptions may be considerable. The assumption made in connection with the author's calculations, judging from his use of the 48-hour oxygen demand as their basis, would appear to fall in the latter category.

In connection with the figures given by the author, relative to the 48-hour oxygen demand of New York sewage, it may be of interest to note that experiments conducted by the U. S. Public Health Service in connection with stream-pollution studies in the Ohio and Illinois Rivers have indicated that at a temperature of 25° cent., an average of approximately 44% of the total oxygen demand is satisfied in 48 hours in normal composite city sewage. This figure, which is based on experiments made on the sewage of Washington, D. C., Cincinnati, Ohio, and Chicago, Ill. (in the last-named case at the outlet of the Drainage Canal), is close to the Metropolitan Sewerage Commission's figure of 48% cited by the author, but considerably lower than the

Adeney figure given. A point of doubt concerning all figures of this kind, where they are based on small-scale laboratory incubation experiments, is as to whether a particular rate as determined in the laboratory would necessarily hold true for the same water or sewage in a natural body of water. An effort is being made, in connection with studies now being conducted by the Public Health Service in the Illinois River, to establish a basis for measuring the rate at which the oxygen demand is actually satisfied in the stream itself, applying principles which have been stated in connection with this discussion.

The curve, shown in Fig. 3, defining the rate of absorption of dissolved oxygen by water at different degrees of saturation, illustrates in an interesting and practical way the relation between these two variables, as determined experimentally. Although the curve does not follow closely the law of velocity of solution previously noted, it would hardly be expected that an experimental curve of the kind would do so, in view of the interference which diffusion and vertical circulation would presumably offer to a measurement of the theoretical relation. It affords a practical basis, however, for interpreting the law under conditions closely approaching those of the experiment, and it is hoped that further work along similar lines can be undertaken. Further information regarding the methods used in experiments would be of much value to investigators in this field.

Finally, it may be worth while to emphasize the point made by Mr. Purdy namely, that in casting up a balance sheet between the oxygen demand and available sources of oxygen to satisfy such demand, the possible influence of intensive biological activities in shallow bodies of water, similar to those of the tidal flats near New York Harbor, can never be safely overlooked. Whenever a marked and fairly regular increase in dissolved oxygen is noted during the day in a particular locality, as exemplified by the author's observations in the Arthur Kill, the presence or absence of aquatic plant organisms capable of liberating oxygen may be a factor of prime importance.

The author has rendered a real service in presenting the results of his study. It is hoped that further studies of the difficult and important problem with which his paper deals, will be made in the future, in order that correlations of fundamental importance in connection with problems involving the self-purification of both streams and tidal bodies of water may be established.

GEORGE A. SOPER,* M. AM. SOC. C. E. (by letter).—The writer is interested in papers which deal with the pollution of New York Harbor, for it is only through the discussion of this greatest of all practical sewage problems that engineers can come to understand the conditions which exist, and form an opinion as to the character of the works which are required to dispose properly of the sewage of the Metropolitan District. For a subject of such great importance to New York City and, in fact, to the whole country, there is a singular lack of understanding of the question, and this applies to the general public and to the Engineering Profession alike.

* Cons. Engr., New York City.

An obstacle to the proper grasp of the elements of the problem lies in the tendency to regard the harbor somewhat as a laboratory vessel or tank concerning which it is easy and safe to make general observations. As a matter of fact, the sanitary protection of the waterways in the Metropolitan District probably offers the most diverse and complicated series of engineering, chemical, and biological problems that has ever been presented. After an experience of eleven years of official connection with these problems, the writer has come to look on dogmatic, unqualified, and sweeping assertions concerning them with considerable impatience.

The author seems not to be one who is willing to confine himself to the quick and easy method of argument, but has taken data from the reports of the Metropolitan Sewerage Commission and, with information of his own collecting, has sought to advance the existing knowledge of the subject by calculations of the sources of oxygen, which can be utilized in finally disposing of the sewage. The fact that the writer cannot fully agree with him in his conclusions, does not destroy his sense of the value of the paper.

That large quantities of oxygen are absorbed from the atmosphere has long been recognized, but no one has gone as far as the author in attributing such a generous share of the renewal to this source. If "the dissolved oxygen in the waters will be depleted until the rate of oxygen absorption from the air equals the rate of oxygen demand of the fermenting organic matter", the question naturally arises, how is it that the oxygen content throughout New York Harbor is falling lower and lower, until, in some of the main divisions, it has recently been reported as absent?

In spite of its many excellences, the paper contains ambiguities and inconsistencies of statement which leave some of the author's views obscure. If these defects were remedied, it is quite possible that the writer would see no reason to differ with him.

H. W. CLARK,* ESQ. (by letter).—There can be little criticism of the conclusion drawn by the author in regard to surface absorption of oxygen, although the writer believes that the clean tidal water saturated with oxygen, or nearly so, coming into polluted harbors is, perhaps, of greater importance than Mr. Gould's figures seem to show. There is a tremendous absorption of oxygen by water when exposed to the air, and especially so when it is ruffled by wind. In the report of the Massachusetts State Board of Health for 1891, the greater absorption of oxygen in water and its absorption to greater depth due to wind action was discussed by the late Dr. Thomas M. Drown, in an article entitled "Amount of Dissolved Oxygen Contained in Waters of Ponds and Reservoirs at Different Depths."

Work on this subject has been done by the writer from time to time, and a discussion in regard to the absorption of oxygen and the purification of sewage due to such absorption, was given in his report to the Charles River Dam Committee in 1902, together with various experiments to show the purification of polluted water by oxygen absorption. Certain of these experiments with fresh water (90% saturated with oxygen), to which was added, in dif-

* Chf. Chemist, Massachusetts Dept. of Public Health, Boston, Mass.

ferent bottles 1, 3, 5, and 10% of strong sewage, showed the exhaustion of oxygen and the development of odors under closed conditions, whereas with surface exposure, the absorption of oxygen to replace that used in purification, was very marked. In this report, after calling attention to the changes occurring after the Charles River Tidal Estuary would be turned into a fresh-water basin, preventing the entrance of sea water saturated, or nearly so, with oxygen, and calling attention to the volume of sewage that would enter it daily, the following statement was made:

"In this last connection, it must be understood that under any condition which can exist in the basin the surface water will be continually changing. The basin lies so that it is exposed to the unrestricted sweep of the prevailing summer wind and even at times of light breeze the change will be quite rapid and hence each day there is a chance for much oxygen to be taken up by the water of the basin in this way."

Mr. E. A. LETTS,* has stated that Dr. Adeney found that 10 days were required to saturate with oxygen a sheet of water with a temperature of 15° cent., 6 ft. in depth, and deprived of all atmospheric gases. In experiments made by the writer in 1912, and described in the report of the State Board of Health for that year, it was shown that quiet water in a body only 7 in. in depth required 7 days to increase from 0.38 parts per 100 000 dissolved oxygen to 0.94 parts per 100 000, or saturation at the temperature of the experiment. The increase was at the rate of 0.08 parts per day. When, however, this shallow vessel contained a small fish, an amount of oxygen equal to 0.26 parts per day was absorbed, or the amount consumed by the fish daily, as had been previously proved. This experiment covered a period of 34 days. In this case, undoubtedly the surface of the water was more or less ruffled by the movements of this fish. Recent experiments by the writer have also seemed to show that, as Adeney has stated, dissolved oxygen streams from the top to the bottom of a liquid. To prove this, a glass cylinder, 10 in. in diameter and 3 ft. deep, was filled with water polluted to such an extent that dissolved oxygen failed to be present. Methylene blue added to this water was decolorized at first, owing to the absence of oxgyen, but as oxygen was absorbed, streams of the blue dye were shown throughout the depth of the water, thus indicating the penetration of the oxygen from the surface downward. This experiment was with an absolutely quiet surface.

GORDON M. FAIR,† ESQ. (by letter).—In May, 1919, the writer conducted a series of experiments on re-aeration in the Laboratory of Sanitary Engineering of Harvard University, under the direction of Professor George C. Whipple, M. Am. Soc. C. E., who was then investigating the pollution of New York Harbor. These experiments contribute some interesting information to Mr. Gould's study and are discussed with the permission and at the suggestion of Professor Whipple.

Two series of tests were run at short notice and with limited equipment; the results obtained were, perhaps, somewhat crude, *conditio sine qua non*, but

* *Journal*, Royal Sanitary Inst., Vol. XXXIII, No. 1.

† Director, Bureau of Statistics and Research, Cuyahoga County Public Health Assoc., Cleveland, Ohio.

warranted an interpretation of surface aeration that seems to be substantiated by recent investigations on sewage disposal and treatment. Four large containers with a capacity of about 12 gal. were filled with Cambridge tap water and freed from oxygen (as far as this was possible) by boiling. The containers were then placed in ice water in order to cool the de-aerated liquid. In the first series of tests, the surface of the water was covered with carbonic acid gas for the purpose of minimizing oxygen absorption from the atmosphere during cooling. As a result, the water became saturated with carbon dioxide, a condition that seemed to affect the results of the first experiment. This proceeding, therefore, was not repeated in the second run, and equally good de-aeration was obtained.

After the temperature of the water had been reduced to 20° cent., and the carbonic acid gas had been blown off the surface, the water was permitted to aerate under the following conditions:

1.—Water surface undisturbed.

2.—Water surface agitated by air current from electric fan; an air velocity of 1 200 ft. per min. (13.6 miles per hour) was obtained in the first test, and a velocity of 750 ft. per min., (8.5 miles per hour) in the second test. The rippling of the water was naturally greater with the higher air velocity.

3.—Water surface agitated by waves produced by balancing the container on a round rod and moving it slowly up and down.

4.—Water surface agitated as under both Conditions (2) and (3).

Dissolved oxygen samples were taken at the beginning and at frequent intervals throughout the test, which, in some cases, extended over 2 and 3 days. The change in dissolved oxygen content permitted the computation of the rate of oxygen absorption by taking into account the surface area and capacity of the container, the time elapsing between samples, and the temperature of the water. A second series of experiments, made in substantially the same manner, gave results more consistent than those of the first series. The results of this second series, expressed in cubic centimeters of oxygen absorbed per square foot of water surface per day and standardized to a temperature of 20° cent., are shown graphically in Fig. 6.

The discrepancies between the two series of results were presumably due to the disturbing influence of the carbon dioxide on oxygen absorption during the first test. This gas probably streamed out of the liquid while the experiment was in progress and, settling over the water surface, prevented aeration whenever it was not removed by the current of air from the fan. The lower wind velocity in the second series of experiments, (750 ft. per min. against 1 200 ft. per min.), which produced only a very slight rippling of the water surface, probably also contributed to the difference in the rate of oxygen absorption by the water exposed to wind action.

In view of the crudity of these simple laboratory tests, the results obtained are best considered in their relation to each other; they should not be regarded as attempted determinations of the actual coefficient of oxygen absorption for wide stretches of wind and wave-swept waters. The absorption values of the undisturbed water, however, are in close agreement with those of the

composite curve shown by the author. Taking the author's figures as a basis for comparison, the influence of wind and wave action is manifested in the writer's first series of tests, by a high rate of oxygen absorption, equal for wave action, to twice the absorption of the undisturbed water, for wind action, to five times, and for wind and wave action combined, to fifteen or twenty times. In the second series of tests, the increase over quiescent water was twofold for wind action and almost tenfold for wave action as well as wind and wave action combined. These ratios seem to remain fairly constant, regardless of the saturation value of the water. In the first experiment, wind action accelerated the oxygen absorption to a greater degree than wave movement; in the second, wave action was practically as effective as wind and wave movement combined. As suggested previously, the presence of carbonic

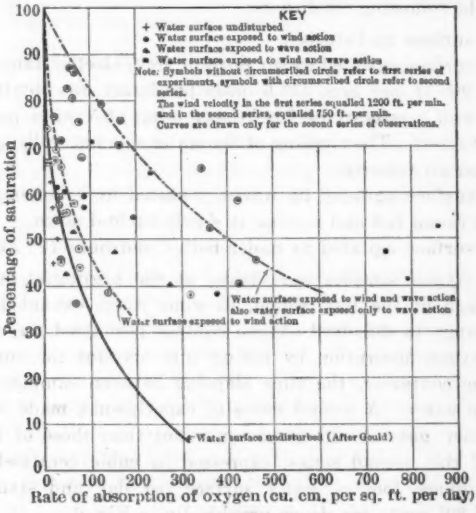

FIG. 6.

acid gas may explain this difference in behavior. The results of the second experiment approached more nearly actual conditions, because normally the quantity of carbon dioxide present in surface water is altogether too small to bring about the conditions obtaining in the first test. The fact that re-aeration increased only slightly under wind action in the second test, the water being practically devoid of carbon dioxide and exposed to a weak air current that caused little disturbance of the water surface, is, therefore, quite consistent with one's expectations; likewise the fact that wave action under these circumstances was about as effective as wind and wave movement combined.

As wind seems to increase aeration chiefly through the induced wave movement, except when a heavy gas overlies the water, there are two principal factors that account for the remarkable acceleration of re-aeration produced whenever the surface of the water is disturbed, namely, the increase in surface

area as a result of wave formation, and the increase in oxygen convection induced by mixing the water and bringing new surfaces of liquid in contact with the atmosphere. The writer's calculations of the surface area of waves show an increase of only 2 to 5% for the primary surfaces of large waves. Taking into account, also, the secondary increase due to the occurrence of smaller waves on the larger ones (that is, rippling of the wave surface), it still remains difficult to explain absorption values as high as those obtained in the experiments, unless it is assumed that the wind is strong enough to produce white-caps and break the water into fine spray. Freely divided drops of spray have a large surface area, which, according to experiments made by Mr. M. C. Whipple, are capable of absorbing oxygen at rates of 100 or even 1 000 times that of quiescent water.

In the laboratory experiments under consideration, the water was not agitated sufficiently to splash and form spray; consequently, the increase in water surface by wave action does not account for the large acceleration of re-aeration. For these experiments, therefore, the factor of oxygen convection, that is, the mixing of the water, bringing new surfaces of liquid in contact with the atmosphere, seems to be the more important one. After observing, a short time ago, the operation of the new mechanical activated sludge plant at Sheffield, England, the writer is inclined to believe that this factor of convection is also the controlling force in the re-aeration of large bodies of polluted water. The Sheffield experiments clearly demonstrated that an exceedingly polluted water—for, after all, sewage is only an extreme case of water pollution—can be kept charged with oxygen by bringing changing surfaces of liquid in contact with the atmosphere. This discovery has influenced the design of the newer, English, air activated sludge plants so that this type of sewage treatment works provides for surface aeration rather than compressed air aeration, the compressed air being used to keep the sludge in suspension and bring new surfaces of liquid in contact with the atmosphere, rather than to secure aeration by bubbling.

The author asks for a thorough investigation of re-aeration, and, in the writer's opinion, the necessity of developing the newer methods of sewage treatment supports this demand.

RICHARD H. GOULD,* ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Allen has asked for further description of the experiments for determining the rate of aeration of waters, as given in the paper. Those points shown on the curve in Fig. 3 and credited to the "Office of James H. Fuertes", were obtained from two series of laboratory experiments. Tap water was freed from oxygen by boiling and a known volume exposed in six small bottles for each series. The contents of a bottle was analyzed at the start of the experiment and at the end of 1 hour, 2 hours, 18 hours, 42 hours, and 8½ days. The results, calculated on the basis of oxygen absorbed per unit area of surface exposed to the air, were plotted, and a curve was drawn through the points. The two series agreed closely, although no particular refinements in laboratory methods were used. From these curves, the rate of absorption of oxygen per unit of

* Prin. Asst. Engr. with James H. Fuertes, New York City.

surface was calculated for several percentages of saturation of the water and the results were plotted as shown in Fig. 3. The points shown on Fig. 3 and credited to the Metropolitan Sewerage Commission, were computed from published analyses.* Three series of analyses for tap water and for sea water were plotted and found to agree closely with each other. A smooth curve was drawn through the points obtained from fresh water and another through those obtained from sea water, and the rate of oxygen absorption for increments of 10% of saturation was computed and plotted as shown.

From lack of knowledge of all the details connected with the various analyses, and the lack of refinement of the methods in other cases, it is not felt that the curve given in Fig. 3 is the last word in showing the true rate of absorption of atmospheric oxygen. It was thought, however, that the values shown might be reasonably near the true values. Additional experiments are desirable, and it is pleasing to note that Mr. Fair has been able to submit results of additional analyses. His values for undisturbed water surface do not deviate greatly from those shown in Fig. 3, and he is able to confirm in a quantitative way the increased aeration due to wind action and wave action, as brought out by Mr. Borst and shown by actual analyses to exist in harbor waters. It is hoped that some member of the Society will soon have occasion to carry out additional experiments showing the affect on the rate of oxygen absorption of wind and wave actions and also of humidity, which is mentioned by some as exerting considerable influence.

Mr. Purdy has called attention to the possible influence of plankton and aquatic plant life in influencing the oxygen content of harbor waters. In New York Harbor and particularly in Newark Bay, sea-weeds, grasses, and sea mosses do not seem to be present to any considerable extent. There is a continual deposition of sludge on the bottom of the Bay and on shallow flats. Without having experimental evidence of the presence, in large quantities, of diatoms and plant life capable of giving off oxygen, it would seem improbable that conditions for their development would be as favorable in Newark Bay as in the instances along the Potomac River cited by Mr. Purdy. The quantity of oxygen liberated by the plankton would be that contained in the carbon dioxide in the waters. The average quantity of carbon dioxide carried by the waters of the Passaic River in July and August has been such that if all its oxygen was liberated by the action of the plankton, it would effect the oxidation of about 7 000 000 gal. of sewage per day, or something less than 5% of the quantity estimated as flowing into Newark Bay. Additional carbon dioxide is formed by the bacterial action, utilizing the dissolved oxygen in the Bay waters. In the absence of definite knowledge of the importance of these various influences, one can only guess as to the total effect. All things considered, it would not be well, perhaps, to attribute a large part of the oxidizing effect to the re-utilization of dissolved oxygen which is made available by plankton. In a final and accurate balance of the various oxidizing influences, this question, of course, should receive due weight.

Mr. Allen and Mr. Hazen have discussed the various factors entering into the purification processes in New York Harbor and of some of the conflicting

* Report of the Metropolitan Sewerage Commission, 1914, pp. 738 *et seq.*

ideas and influences that have been current. There seems to be a general feeling that in casting a balance of the purifying influences in the harbor, the effect of the oxygen carried by the tide has not been given due weight. There are tremendous volumes of water flowing into and out of the harbor on each tidal cycle and several capable authorities seem to agree substantially on the amount of these flows. The fact that salt water works its way into the harbor and indeed, to a certain extent, as far north as Newburgh, N. Y., against the continued outward flow of fresh water from the Hudson River, shows that a large quantity of new salt water comes into the harbor daily. The water in the Upper Bay, during the summer months, is commonly 78% sea water and 22% land water. If the volume of this 22% land water is that given by Mr. Allen as the August flow of the Hudson River, the total daily flow of combined salt water and fresh water from the Lower Bay would be about 5 050 000 000 cu. ft. per day, which is not greatly in excess of the figures for August, given by Mr. Hazen.* In this connection, however, it might be well to note the statement† of H. De B. Parsons, M. Am. Soc. C. E., in discussing the land and sea water flowing into and out of the harbor, that,

"the quantity of 'new sea-water' is never a large proportion of the total quantity flowing on a flood tide. This 'new sea-water' is only new off places situated near the ocean, and is not new at such places as the Upper Bay, Fort Washington Point, Tarrytown, East River, or Newark Bay. At these places the 'new sea-water' is really water which has not been at the place on the previous tide, but comes from some other part of the harbor."

Even at The Narrows, the water entering on the flood tide is not fresh, unpolluted sea water saturated with oxygen, but from all available analyses it seems rather to be a mixture of fresh and polluted waters with its oxygen already somewhat depleted, and, no doubt, containing organic matter with a certain oxygen demand.

The full force of Mr. Allen's statement that the computation of the oxygen supply to the Upper Bay through The Narrows by the excess of the saturation by the flood over that of the ebb currents would be misleading, is not fully apparent. The Metropolitan Sewerage Commission has published in its reports several excellent cross-sections of The Narrows in which dissolved oxygen samples were taken at all depths and which seem to give fair averages of the dissolved oxygen content of the waters flowing in the currents at the particular time that these cross-sections were taken. Where so many conflicting influences are functioning, it would seem that careful and extensive oxygen determinations and their use would represent the surest method of arriving at satisfactory results.

Perhaps the most complete series of cross-sections at The Narrows, showing both the flood and ebb currents, are those taken on September 26th, 1911, the average percentage of saturation at each cross-section being plotted in Fig. 7, together with two additional series taken in July, 1913. Each point represents about fifteen analyses fairly uniformly spaced throughout the cross-section of The Narrows and should be representative. The importance of

values throughout the entire tidal cycle for the correct determination of average conditions is indicated. The curve for September 26th, 1911, shows considerable excess oxygen carried in the flood current over the ebb current; that for July 3d, 1913, indicates little difference in the two currents, whereas that for July 24th, 1913, shows the ebb current to carry the excess of oxygen. The two series of cross-sections taken in July, 1913, do not support the proposition that a large excess of oxygen is supplied to the Upper Bay through the tides. That for September 26th, 1911, is most complete in its data in reference to the oxygen content on both currents, and presents the most favorable record indicating a large supply of oxygen through the tidal currents to the Upper Bay.
